Testing for Association in 2 × 2 Contingency Tables With Very Small Sample Sizes

Gregory Camilli and Kenneth D. Hopkins
Laboratory of Educational Research
University of Colorado

Applied statistics textbooks generally recommend the use of the chi-square tests of homogeneity and independence with 2 × 2 contingency tables only when the expected frequency of each cell is five or more. Recent research has shown this rule-of-thumb criterion to be unnecessarily restrictive, but has not explored the accuracy of the chi-square tests when the total number of observations is less than 20 or when the expected frequencies fall well below one—the primary issues considered in this article. The chi-square tests of homogeneity and independence were found to provide reasonably accurate estimates of Type I error probability for $N \geq 8$. Certain alternatives to the chi-square tests are considered.

There are three distinct models for deriving probability statements for 2 × 2 contingency tables (Kendall & Stuart, 1967, pp. 549–555). In Model 1, a researcher specifies both sets of marginal frequencies before the data are collected; this is Fisher's exact test. In Model 2, one set of marginal frequencies is fixed, the other being free to vary randomly; this is termed a test of *homogeneity*. In Model 3, neither set of marginal frequencies is fixed; this is typically described as a test of *independence*. The chi-square test has been shown to provide approximate, but accurate, probability estimates in Case 2 (test of homogeneity) and Case 3 (test of independence) for sample sizes as small as $N = 20$ if the Yates correction is not applied (Camilli & Hopkins, 1978; Roscoe & Byars, 1971). The accuracy of chi-square tests of homogeneity and independence with sample sizes smaller than 20 does not appear to have been explored. Although Model 1 is rarely consonant with empirical data, the chi-square test in which the continuity correction has been made estimates probabilities associated with Model 1. In Model 2 or Model 3 chi-square applications, the continuity correction should not be applied, since it decreases the accuracy of the related probability statements (Camilli & Hopkins, 1978).

Requests for reprints should be sent to Kenneth D. Hopkins, Laboratory of Educational Research, University of Colorado, Boulder, Colorado 80309.

Method

This study examined the effects of the four independent variables listed below on the actual proportion of Type I error in relation to the nominal alpha values of .10, .05, and .01: (a) total number of observations, N, in the 2 × 2 contingency table (N = 4, 8, 12, 16, and 20); (b) row marginals fixed (Model 2) versus random (Model 3); (c) relative frequencies of the N observations in the two row categories when row marginal frequencies ($n_{1\cdot}$ and $n_{2\cdot}$) were fixed ($n_{1\cdot}/n_{2\cdot}$ = 1.0 and .33); when row frequencies were random, the row marginal proportions varied randomly about the parameters $\pi_{1\cdot}$ and $\pi_{2\cdot}$, with $\pi_{1\cdot} = 1 - \pi_{\cdot 2}$ = .500, .707, and .794; and (d) proportion of N observations in the two random column categories $\pi_{\cdot 1}$ and $\pi_{\cdot 2}$ ($\pi_{\cdot 1} = 1 - \pi_{\cdot 2}$ = .500, .707, and .794). (The proportions employed by Roscoe & Byars, 1971, and Camilli & Hopkins, 1978, were used in this study to facilitate comparisons of findings.)

Results

Model 2: Chi-Square Test of Homogeneity

The actual proportions of the 10,000 replications in which the observed chi-square value exceeded the critical chi-square value at nominal alpha levels of .10, .05, and .01 are given in the upper portion of Table 1 for selected Model 2 chi-square applications. For example, the second row of Table 1 indicates

[a] Pseudorandom numbers were generated by the International Mathematical and Statistical Libraries subroutine GGUB (IMSL, 1977). In addition to the 25 simulations reported in Table 1, 25 additional simulations were performed with row and column parameters falling between the extremes represented in Table 1.

[b] $\sigma_p = .0030$, .0022, and .0010 for $\alpha = .10$, .05, and .01, respectively.

[c] In certain instances of the 10,000 replications in which the expected cell frequencies were very small, the random number generating process yielded a column with a zero frequency, hence the chi-square was not computable. One can subtract this figure from 10,000 to recalculate the proportion of Type I errors in the sample space in which the chi-square was computable.

[d] Because of the discreteness in the empirical sampling distributions, the proportions of Type I errors are identical at $\alpha = .10$ and $\alpha = .05$ (and in all other simulations in which $N = 4$).

that when the 2 × 2 contingency table contained $N = 8$ observations divided equally between the two rows ($n_{1.} = n_{2.} = 4$) and when the proportion of N observations falling in each column varied randomly about $.5 = \pi_{.1} = \pi_{.2}$, the observed proportions of Type I errors ($\hat{\alpha}$) were .0715, .0715, and .0058 at the nominal alpha values of .10, .05, and .01, respectively.

Model 3: Chi-Square Test for Independence

Selected results from applications of Pearson's chi-square to null situations in which both row and column proportions differed randomly from the specified parameters $\pi_{1.}$ and $\pi_{.1}$ are given in the lower portion of Table 1. In all 50 simulations (25 of which are reported in Table 1), the expected frequencies

of at least two of the four cells were five or less; the expected frequency of one or more cells was extremely small (one or less) in 24 of the simulations.

For both models, when $N \geq 8$, the nominal alpha values were reasonably accurate at $\alpha = .05$ (the proportion of Type I errors varied between .0222 and .0715) and $\alpha = .01$ (the proportion of Type I errors varied between .0047 and .0228). For $N = 4$, the accuracy at $\alpha = .10$ was adequate, but for $\alpha = .05$ and $\alpha = .01$, accuracy was very poor. The issue of power is critically important. A later section demonstrates that when the two factors are very highly correlated, the statistical power of the chi-square test with very small Ns is very low. But alternatives can provide a more powerful test under certain conditions.

Alternatives to 2 × 2 Chi-Square Tests

To illustrate the first alternative, consider a 2 × 2 contingency table in which $N = 10$ and $n_{11} = 4$, $n_{12} = 1$, $n_{21} = 1$, and $n_{22} = 4$, hence $n_{1\cdot} = n_{2\cdot} = n_{\cdot 1} = n_{\cdot 2} = 5$. The probabilities for this particular configuration of frequencies for Models 2 and 3 are related to the probability of Model 1 by binomial multipliers (Kendall & Stuart, 1967, pp. 551–555):

$$p_1 = \frac{n_{1\cdot}!n_{2\cdot}!n_{\cdot 1}!n_{\cdot 2}!}{N!n_{11}!n_{21}!n_{12}!n_{22}!}; \qquad (1)$$

$$p_2 = p_1\binom{N}{n_{\cdot 1}}\pi_{\cdot 1}{}^{n_{\cdot 1}}(1 - \pi_{\cdot 1})^{N-n_{\cdot 1}}; \qquad (2)$$

$$p_3 = p_2\binom{N}{n_{1\cdot}}\pi_{1\cdot}{}^{n_{1\cdot}}(1 - \pi_{1\cdot})^{N-n_{1\cdot}}. \qquad (3)$$

Using Equation 1, p_1 (Fisher's exact probability) is found to be .0992. Using Equations 2 and 3 and supposing that $\hat{\pi}_{\cdot 1} = \hat{\pi}_{1\cdot} = .5$, the probabilities of the observed 2 × 2 configuration can be determined:

$$\hat{p}_2 = p_1\left(\frac{10!}{5!5!}\right)(.5)^{10} = .0992(.2461) = .0244$$

and

$$\hat{p}_3 = \hat{p}_2(.2461) = .0060.$$

But these probabilities are for observing this particular frequency configuration in the sample space. The random marginal frequencies allow many more possible frequency configurations under Model 2 than under Model 1 and many more still under Model 3. Indeed, unless N is very small (10 or less), the process of enumerating the various frequency configurations, and hence deriving a probability distribution, is not practicable without the assistance of computer programs. Furthermore, this "exact" distribution will only be as useful as $\hat{\pi}_{1\cdot}$ and $\hat{\pi}_{2\cdot}$ are accurate.

A modification of Fisher's exact test, proposed by Tocher (1950), can be used to compensate for the discreteness of sampling distributions if one desires to make decisions at precise conventional alpha values such as $\alpha = .05$. In Tocher's procedure, one selects alpha (α) and then calculates the cumulative Model 1 distribution for the given configuration: L_1 is defined as the probability of all more extreme configurations (in our example, $n_{11} = n_{22} = 5$ and $n_{12} = n_{21} = 0$), and $L_1 = .0040$ using Equation 1); L_2 is the probability of the obtained configuration (.09921) plus L_1, hence $L_2 = .1032$. If $L_2 \leq \alpha$, H_0 is rejected; if $L_1 > \alpha$, H_0 is tenable. But in situations like ours in which $L_2 > \alpha > L_1$, the ratio R is determined: $R = (\alpha - L_1)/(L_2 - L_1)$. In our example,

$$R = (.05 - .004)/(.1032 - .004) = .464.$$

A random number (X) is then selected from a uniform distribution within the interval (0, 1). If $X \leq R$, H_0 is rejected; otherwise H_0 remains tenable; or given our data set, the probability that H_0 will be rejected is .464. The exact level of significance equals $XL_2 + (1 - X)L_1$.

Tocher's test (also known as the randomized exact test) has been shown to be the uniformly most powerful unbiased test for all three models (Kendall & Stuart, 1967, p. 554; Tocher, 1950). The degree of difference in power does not seem to have been explored for very small Ns.

Power Comparisons

The relative power of the chi-square and Tocher's exact test was compared for 12 Model 2 and Model 3 situations that were a subset of the original 50 simulations, except that the cell proportions (π_{ij}) varied from .4 to .1. At $\alpha = .05$ and at $N = 8$, the power efficiency of the chi-square ranged from .18 to

.64, with the lesser power differences occurring with larger $\pi_{11}/\pi_{1\cdot} - \pi_{21}/\pi_{2\cdot}$ values. The differences in power were much less for $12 \leq N \leq 20$, with the power efficiency of the chi-square ranging from .64 to 1.05. The gain from Tocher's test is negligible if $N \geq 20$ (Starmer, Grizzle, & Sen, 1974). The absolute power of the chi-square or the Tocher tests exceeded .80 only when effects were very large (e.g., $\pi_{11}/\pi_{1\cdot} = .8$ and $\pi_{21}/\pi_{2\cdot} = .2$) and $N \geq 16$ with $\alpha = .05$. Researchers working with precious observations that may limit N should probably relax alpha to .10 and make directional tests to increase power.

Many behavioral researchers will find Tocher's test philosophically objectionable in spite of its greater power, since the gain in power is affected not by data but by the "luck of the draw."

Conclusions

In 2×2 contingency tables, the chi-square test provides a quick and reasonably accurate Type I probability statement for tests of homogeneity or tests of independence if $N \geq 8$. If $N < 5$, $\alpha = .10$ should be used, since $\alpha = .05$ and $\alpha = .01$ become very inaccurate.

Fisher's exact test can also be employed. but is very conservative for Model 2 and Model 3 applications (Camilli & Hopkins, 1978). The most powerful, but philosophically controversial, alternative is Tocher's exact test, which has greater power than the chi-square test, especially when $N < 20$. To increase power if N cannot be increased, researchers should consider relaxing alpha to .10 or more and making one-tailed tests.

Psychological Control of Essential Hypertension: Review of the Literature and Methodological Critique

Peter Seer
Department of Psychiatry, University of Auckland, Auckland, New Zealand

Recent studies (1971–1978) that investigated psychological approaches to the treatment of essential hypertension are reviewed. Twenty studies that use techniques of biofeedback, relaxation, and meditation training are summarized in table form. They are subjected to a detailed methodological critique, and suggestions for methodological improvements and directions for future research are proposed. Most experiments demonstrated blood pressure reductions too small to be of clinical significance. A combination of biofeedback and relaxation/meditation with other behavioral techniques appears most promising, and suggestions for a more comprehensive approach to assessment and training are made. Although studies comparing biofeedback and relaxation/meditation were inconclusive, relaxation/meditation is suggested to hold more promise because it requires no sophisticated technology and has been reported to simultaneously reduce other stress-related complaints.

In recent years we have witnessed an increasing interest in the psychological control of essential hypertension and of disease in general. This trend appears to be related to a shift in disease patterns. On the one hand, we can observe a drastic reduction in contagious diseases and, on the other hand, a dramatic increase in degenerative disorders such as coronary heart disease and essential hypertension (Stoyva, 1976). There is an extensive body of research indicating that essential hypertension can be related to dysfunctional habits of living and of responding to an environment of ever increasing complexity (Gutmann & Benson, 1971; Henry & Cassel, 1969). Further related to this trend is the growing recognition that the pharmacological treatment of essential hypertension has many undesirable side effects (Bulpitt & Dollery, 1973) and is far less effective than drug advertisements lead one to believe (Kannel & Dawber, 1973; LoGerfo, 1975). The development and scientific study of nondrug alternatives in the control of essential hypertension is therefore highly desirable. Psychological approaches such as biofeedback, relaxation, and meditation constitute such an alternative. The purpose of this article is to present a review of recent research in this field (1971–1978), to critically evaluate its methodology, to make special recommendations for minimal methodological requirements, and to make suggestions for future research.

Definition, Incidence, and Classification of Essential Hypertension

Hypertension has become an epidemic of major proportions in western society. Estimates of its prevalence vary from 10% to as high as 30% of the total adult population, depending on the definition of what constitutes high blood pressure (Stamler, Stamler, Riedlinger, Algera, & Roberts, 1976). Although there exists considerable disagreement over the definition of hypertension, it is safe to say that for persons of up to 50 years of age, a blood pressure of 145/95 mmHg would be classified as mild hypertension. Hyperten-

I wish to thank John Raeburn and John Spicer for their critical reading of earlier drafts of the manuscript.

Requests for reprints should be sent to Peter Seer, who is now at Fachbereich Psychologie, Rehabilitationszentrum, Südring 15, 7812 Bad Krozingen, West Germany.

sion in its early stages is asymptomatic, that is, it is not accompanied by any overt warning signs. Consequently, as many as 50% of all cases of hypertension go undetected (Onesti, Kim, & Moyer, 1973). More than 90% of all cases of hypertension are of unknown etiology; they fall into the category of primary or essential hypertension. The remainder, labeled secondary hypertension, is due to identifiable renal, endocrine, neurogenic, and other disorders; this latter category of secondary hypertension will not be discussed in this article.

Hypertension as a Major Risk Factor

It has been firmly established that moderate to severe hypertension increases morbidity as well as mortality from many diseases, especially cardiovascular disorders. The most comprehensive and conclusive epidemiological study in this field is the Framingham study (Kannel, 1976), which has been in continuous operation since 1948. This study has found hypertension to be one of the most robust predictors of such life-threatening disorders as myocardial infarction, congestive heart failure, stroke, and damage to kidneys, eyes, and other organs. Risk was found to increase proportional to increases in blood pressure, and hypertensives were found to be three times more likely to develop cardiovascular disease than normotensives. Both systolic and diastolic blood pressure were found to be of equal importance.

If we consider that, for example, in the United States more than 50% of all deaths are linked to cardiovascular and cerebrovascular disorders, and if we consider the enormous suffering of those affected and the staggering costs involved, it becomes obvious that prevention and treatment of hypertension and other known risk factors is of paramount importance.

Consequences of Reducing Elevated Blood Pressure

The importance of controlling moderate to severe hypertension for the reduction of morbidity and the prolongation of life has been most convincingly demonstrated in two major double-blind studies by the Veterans Administration Cooperative Study Group on Antihypertensive Agents (1967, 1970). Results clearly indicated that in comparison to experimental subjects who received active pharmacological treatment, a significantly higher percentage of placebo group subjects developed congestive heart failure, stroke, renal damage, retinopathy, and accelerated hypertension. However, pharmacological treatment did not significantly reduce the incidence of myocardial infarction.

Medical opinion differs considerably with regard to the value of the treatment of mild hypertension, in the absence of clear evidence of its general preventative worth. However, the control of even small blood pressure elevations has been shown to reduce cardiovascular disease in subjects who simultaneously display other cardiovascular risk factors such as excessive weight, smoking, and elevated cholesterol levels (Kannel, 1976).

Psychophysiological View of Essential Hypertension

Despite some 40 years of intensive research into the mechanisms and causes of essential hypertension, its etiology is still unknown. A number of physical correlates such as hereditary predisposition, salt intake, overweight, and abnormalities in the renin-angiotensin system (Kannel & Dawber, 1973) have been isolated, but researchers disagree widely as to their respective importance.

Temporary rises in blood pressure in response to events that are subjectively perceived as exciting, demanding, or distressing have been observed. Essential hypertension has been found in people whose adaptive capabilities had been overtaxed in situations such as natural disaster or war, hazardous work environments and excessive work pressures, job loss and unemployment, migration and urbanization, and others. Further, research has shown that sustained blood pressure elevations can be produced experimentally in animals by prolonged elicitation of the emergency reaction, using such procedures as electrical stimulation of the hypothalamus, exposure to various aversive stim-

uli, classical and operant conditioning, and disruption of normal social interrelationships. These blood pressure elevations were found to persist even after the termination of the aversive event. The role of psychosocial factors in essential hypertension has been reviewed by Gutmann and Benson (1971) and Henry and Cassel (1969).

The apparent role of psychosocial factors has led to the development of psychological approaches to the treatment of essential hypertension. These approaches are usually based on a psychophysiological model in which the repeated and prolonged elicitation of the "emergency reaction" (Cannon, 1932) with its characteristic blood pressure lability eventually leads to stabile hypertension in predisposed individuals (Gutmann & Benson, 1971; Henry & Cassell, 1969; Stoyva, 1976). Most studies attempting to control essential hypertension with the psychological techniques of relaxation/meditation and biofeedback aim at reducing the sympathetic nervous system activity that mediates the emergency reaction. It is important to stress that the exact mechanism linking transient rises in blood pressure with sustained elevations is still unknown and that other models can also be used to understand the disorder.

Description of Psychological Techniques Used in the Control of Essential Hypertension

The most widely researched psychological approaches to the control of essential hypertension fall into two major groups, namely, relaxation/meditation and biofeedback.

Relaxation/Meditation

Progressive relaxation. Among the approaches explicitly aimed at producing physical relaxation, one of the most widely used is Jacobson's (1970) "progressive relaxation." Here, the person is instructed to tense and relax various groups of striate muscles throughout the body, starting, for example, with the hands and arms and then progressing to facial muscles and muscles in the trunk and legs. It is worth mentioning that Jacobson (1939) was the first to observe decreases in blood pressure concomitant with muscular relaxation. Progressive relaxation is also an integral part of "metronome-conditioned relaxation," a technique developed by Brady (1973). Here, the person is first taught to tense and relax major muscle groups. This is followed by more general instructions to "re-lax and let go" paced by a metronome set at 60 beats/min.

Meditation techniques. Meditation techniques, as a rule, were conceived within a particular philosophical and religious context. Only recently have they been used outside this context or been combined with various behavior change methods (Shapiro & Zifferblatt, 1976). Meditation techniques are difficult to define as a whole; only the "concentrative" meditation techniques will be considered here. (For a detailed discussion of meditation from a psychological point of view, see Naranjo & Ornstein, 1971.) Their common feature seems to lie in learning to direct one's attention toward a "mental device" (Benson, 1975) or a focus with which the student becomes passively absorbed. A variety of mental devices such as mantras, chants, prayers, visual symbols, or one's breathing or heartbeat are used in the various meditation techniques. Their function is to reduce or eliminate conceptual thinking ("the mental chatter") and to facilitate the development of an encompassing focus on the present moment and concomitant feelings of calm and relaxation. A common phenomenon in both relaxation and meditation techniques is that the practitioner frequently finds his or her attention shifting away from the mental device toward unrelated thoughts, ideas, images, preoccupations, worries, or sensations. These task-irrelevant thought processes are usually not dealt with satisfactorily in the relaxation techniques, whereas the meditation approaches commonly contain explicit instructions for dealing with them.

One of the more common meditation techniques is attention to the ingoing and outgoing flow of one's breath without controlling it. This technique of breath meditation has been popularized and simplified for use with hypertensive patients by Benson (1975) and

has been applied in several hypertension studies. It requires the person to think of the number 1 (or count up to higher numbers) with each exhalation and to return to breath counting whenever distractions occur.

The techniques described so far all involve attending to physical sensations or processes (e.g., breathing). In transcendental meditation (TM; Mahesh Yogi, 1968) a mantra or meaningless sound is introduced as an attentional focus, and the person is taught to repeat the sound mentally in an effortless way.

Physiological effects and active components of relaxation/meditation techniques. A considerable amount of research data on the physiological effects of relaxation/meditation has been accumulated in recent years. Results clearly indicate that physiological effects are not consistent across different forms of relaxation, and meditation and may even differ within a given technique depending on such variables as mode of instruction, context within which the technique is taught, number and length of training sessions, and type of subject population (Woolfolk, 1975). Regarding this latter variable, Davidson and Schwartz (1976) have convincingly argued that different clinical problems manifest themselves in different modes and physiological systems. Therefore, they may require different relaxation/meditation techniques that specifically respond to the involved cognitive, somatic, or attentional processes.

However, there is considerable evidence that common to these techniques is the elicitation of a general physiological pattern that Stoyva and Budzynski (1974) termed "cultivated low arousal." It is characterized by decreases in pulse and respiratory rate, decreases in muscle tonus and oxygen consumption, and increases in skin resistance. This "relaxation response" (Benson, 1975) is seen as incompatible with and counteracting the emergency reaction. Its frequent elicitation is assumed to lead eventually to a reduction in sympathetic activity and consequently to a lowering of blood pressure.

Benson (1975) defined four components of the common active ingredients of relaxation/meditation: (a) a quiet environment, (b) a decreased muscle tonus, (c) a passive attitude, and (d) the restriction of one's attention to a mental device. This latter component is generally seen as most important in explaining the mechanisms that underlie relaxation/meditation (Naranjo & Ornstein, 1971). There is a great need for more research, as the only well-controlled study (Smith, 1976) found that neither a mental device nor a passive attitude were necessary components of meditation.

Common to all relaxation/meditation techniques is that they require the student to intersperse his or her ongoing activities once or twice daily with a 15–20-minute period of just sitting quietly. This component alone may sufficiently explain the observed changes. Several studies comparing the physiological short-term effects of TM with a control condition of just sitting found that they both resulted in comparable physiological changes (Travis, Kondo, & Knott, 1976; Treichel, Clinch, & Cran, 1973; Walrath & Hamilton, 1975).

Biofeedback

In contrast to the relaxation/meditation techniques, biofeedback requires a highly sophisticated technology that has been developed only in recent years. In blood pressure biofeedback training, pressure is recorded on a continuous or noncontinuous basis, and the information is fed back to the subject in the form of a light and/or sound signal or by letting subjects directly observe their blood pressure record. This allows the subject to become aware of fluctuations in blood pressure and to learn to exercise voluntary control.

Constant cuff technique. Shapiro and his associates (e.g., Shapiro, Tursky, Gershon, & Stern, 1969) have made the most important contribution in this field with their "constant cuff" method that allows continuous, beat-by-beat feedback of blood pressure. It involves mounting a crystal microphone inside a standard pressure cuff and placing it over the brachial artery. The cuff is inflated and set at a constant pressure close to the person's average systolic or diastolic blood pressure. Whenever the person's blood

pressure rises above this set level, a Korotkoff sound can be detected by the microphone. With each beat of the heart, the person receives information (yes–no feedback) as to whether his or her blood pressure is above or below the set average blood pressure (binary feedback). After a trial of 50 consecutive heartbeats, the cuff is deflated for 30 sec and then set at a new level depending on the average blood pressure in the previous trial. One session consists of 25 to 30 trials. Shapiro et al. (1969) and Shapiro, Schwartz, and Tursky (1972) were the first to show that small but reliable changes in systolic and diastolic blood pressure could be achieved with this method in normotensive volunteer subjects. (For a review of blood pressure biofeedback studies with normotensives, see Blanchard & Young, 1973.) Benson, Shapiro, Tursky, and Schwartz (1971) were the first to demonstrate the potential usefulness of blood pressure biofeedback training in the treatment of essential hypertension. Since then several other blood pressure biofeedback studies have been conducted, which are presented in the following section.

The constant cuff method has recently been further improved (Elder, Longacre, Welsh, & McAfee, 1977) by adding a tracking device that monitors blood pressure beat by beat and automatically adjust cuff pressure every three to four heartbeats. Two pressure cuffs, one on each arm, that are alternately inflated for 100 sec are used. Feedback is given via an audible tone that changes in pitch with fluctuations in blood pressure. So far this method has only been reported in experiments with normotensives (Elder, Welsh, Longacre, & McAfee, 1977) but is likely to be used with hypertensive subjects in the near future.

Pulse wave velocity technique. Pulse wave velocity as an indirect measure of mean arterial pressure has recently received considerable attention (e.g., Gribbin, Steptoe, & Sleight, 1976). It has also been used for feedback purposes with essential hypertensives (Walsh, Dale, & Anderson, 1977). In Walsh et al. pulse wave velocity was determined by measuring the pulse transit time between the heart's right ventricular action and the finger pulse. It was fed back to the subject both auditorily, in the form of a tone that became higher or lower as the pulse transit time increased or decreased, and visually, on an oscilloscope (analogue feedback). Pulse transit time has been found to relate inversely to mean arterial pressure (Steptoe, Smulyan, & Gribbin, 1976). Despite its great advantage of avoiding the intrusive effects of constant cuff pressure and repeated cuff inflations, this technique has so far not been applied on a larger scale with essential hypertensives.

Noncontinuous blood pressure feedback techniques. Two noncontinuous feedback techniques have been studied in the control of essential hypertension. Elder, Ruiz, Deabler, and Dillenkoffer (1973) applied a blood pressure recorder that automatically measured diastolic blood pressure every 2 min for a total of 20 successive determinations. Subjects received a red-light signal (and verbal praise) contingent on increasingly larger blood pressure reductions. Subjects in Shoemaker and Tasto's (1975) experiment were able to directly observe their blood pressure recording at 90-sec intervals via a mirror placed above the chart recorder. Two straight lines representing the person's pretrial average systolic and diastolic blood pressures were superimposed on the recording, and subjects were instructed to lower their blood pressure so that the recorded blood pressure would fall below the lines.

Noncontinuous blood pressure feedback has the disadvantage of not being sufficiently sensitive to cope with the inherent variability of blood pressure. Shannon, Goldman, and Lee (1978), comparing three types of systolic blood pressure feedback with normotensive subjects, found continuous (beat-by-beat) binary feedback clearly superior to a relatively continuous proportional and a noncontinuous (75-sec intervals) proportional feedback condition. This suggests that the greater the time lag between beat-by-beat blood pressure changes and feedback, the less effective is the technique.

Physiological effects and active components of blood pressure biofeedback. Al-

though a great number of experiments with normotensive subjects have been conducted to tease out the essential ingredients in blood pressure feedback, the exact mechanisms and processes involved are still unknown. Whereas the relaxation/meditation approaches aim at an indirect control of blood pressure via a generalized relaxation response, blood pressure biofeedback aims at specifically or directly altering blood pressure as such. But experimental data are inconsistent. Some researchers have confirmed this specificity of learned blood pressure control (e.g., Kristt & Engel, 1975), whereas others have reported concomitant changes in other cardiovascular parameters (e.g., Fey & Lindholm, 1975).

It is generally assumed that the beat-by-beat feedback of blood pressure is the most important element in the technique. However, there is experimental evidence that normotensive and hypertensive subjects can change blood pressure by instruction alone, that is, by simply being told to change blood pressure in the desired direction without instructions on how to achieve this. Redmond, Gaylor, McDonald, and Shapiro (1974), using essential hypertensives as subjects, found instructions alone to be effective in reducing systolic and diastolic blood pressure by 8–14 mmHg and 6–11 mmHg, respectively. Results with normotensives have been inconsistent. In Steptoe's (1976) experiment, normotensive subjects who received instructions alone reduced blood pressure equally as effectively as subjects who, in addition, received pulse wave velocity feedback. The addition of exteroceptive feedback, however, enhanced the increase condition. In a subsequent study, Steptoe (1977) controlled for environmental stimulation by exposing subjects in the instruction-only group to identical visual displays as feedback subjects. Results favored the feedback condition that produced greater increases in pulse transit time and by inference, greater decreases in mean arterial blood pressure. Much more could be said about this issue, but it would be beyond the scope of this article. (For a detailed discussion, see Brener, 1974, and Shapiro, 1977.)

More research is necessary to determine the active ingredients in blood pressure biofeedback training. The role of attentional, cognitive, and imagery processes as well as the role of reinforcement and individual differences is far from clear. To develop the most effective blood pressure technique, studies are needed that compare the constant cuff and the pulse velocity techniques, continuous and noncontinuous, binary and proportional feedback, and systolic and diastolic blood pressure feedback.

Electromyograph (EMG) and Galvanic Skin Response (GSR) feedback. EMG and GSR feedback, alone or in combination with other techniques, have also been studied in the control of essential hypertension. These techniques do not aim at specifically controlling blood pressure but rather aim at facilitating a general relaxation response. In two unpublished studies (Love, Montgomery, & Moeller, Note 1; Montgomery, Love, & Moeller, Note 2) subjects were trained in EMG feedback, progressive relaxation, and autogenic training; Patel (1973, 1975a) and Patel and North (1975) combined EMG and GSR feedback with various relaxation/meditation techniques.

Review of the Literature on the Psychological Control of Essential Hypertension

The 21 most recent and important single-group and between-groups studies in the field are reviewed and summarized in table form. They have been grouped into the following four categories: (a) blood pressure biofeedback studies (Table 1); (b) relaxation/meditation studies (Table 2); (c) mixed studies, that is, studies in which various feedback and relaxation/meditation techniques have been combined (Table 3); and (d) comparative studies, that is, studies comparing blood pressure biofeedback and relaxation/meditation training (Table 4). These tabular presentations are followed by a detailed methodological critique including suggestions for future research and a discussion of results.

Methodological Critique

A careful inspection of the tables clearly reveals that most of the reviewed studies

have methodological faults, many of them serious ones. A definitive evaluation of the benefits of psychological procedures in the control of essential hypertension is therefore not possible. The following methodological discussion not only points out the faults in these studies but also suggests methodological requirements for future research.

Subject selection. In many of the studies, subject-selection criteria were not reported. For example, length of time a person had been diagnosed as essential hypertensive, age limits, and the required blood pressure level for inclusion into the experiment were often not defined. Some researchers worked with young subjects in whom hypertension is a rare phenomenon (e.g., the average age of subjects in the Stone and DeLeo, 1976, study was 28 years) or with borderline hypertensives (e.g., Shoemaker & Tasto, 1975; Surwit, Shapiro, & Good, 1978). Also, in several cases the diagnosis of essential hypertension was not verified (e.g., Elder & Eustis, 1975). It is recommended that subject samples be homogeneous with respect to (a) an established diagnosis of essential hypertension, (b) a minimum hypertension history, and (c) a minimum pretrial blood pressure.

Concurrent pharmacological treatment. Hypotensive medication and tranquilizers were being taken by subjects in 14 out of the 21 studies. In most studies, drug dosages were systematically stabilized or decreased during the training period. In some investigations, however, drugs or drug dosages were changed for medical reasons unrelated to the research project during the training period (Taylor, Farquhar, Nelson, & Agras, 1977) or during follow-up (Blackwell et al., 1976). This, of course, makes a meaningful interpretation of data difficult. It is possible that certain hypotensive drugs interact with various training procedures, but this has not yet been researched. Deabler, Fidel, Dillenkoffer, and Elder (1973) trained both a drug and no-drug group in progressive relaxation and hypnosis and found no apparent Drug × Training interaction. Unfortunately, no statistical analyses were performed, and the overall quality of the study was poor. One other aspect worth mentioning here is that subjects on medication who participate in biofeedback or relaxation/meditation training may change their drug-taking behavior as a result of the training. So far, drug compliance has not been investigated or reported in any of the relaxation/meditation or biofeedback studies. To avoid serious interpretative problems, it is recommended that investigators treat subjects who receive medication as a distinct group from those who do not.

Baseline assessment of blood pressure. As mentioned before, blood pressure responds to a great variety of environmental and internal factors and exhibits considerable diurnal and beat-to-beat variability. Dollery (1973) has shown that systolic blood pressure during a 24-hour period can be as low as 65 mmHg during sleep and as high as 170 mmHg (and over) during maximal exertion. Shapiro and Surwit (1976) mention that a series of measurements taken every half minute can have a range of up to 30 mmHg. It is well documented (Dunne, 1969; Pickering, 1968) that persons react to the taking of blood pressure with elevations in pressure. In the course of repeated assessments, as subjects adapt to the laboratory situation, blood pressure typically decreases.

In the studies reviewed, several researchers report no baseline period other than the measurement of blood pressure immediately prior to the first training session (Deabler et al., 1973; Elder & Eustis, 1975; Goldman, Kleinman, Snow, Bidus, & Korol, 1975; Kristt & Engel, 1975; Patel, 1973; Walsh et al., 1977; Hager & Surwit, Note 3), or they reported baseline measures for less than 1 week (Elder et al., 1973; Patel & North, 1975; Shoemaker & Tasto, 1975; Surwit et al., 1978). It is highly likely that in some studies, training effects were confounded with blood pressure variability and the effects of adaptation and resting. In single-case experimental research, measurements of blood pressure should be repeated until they stabilize. No clear guidelines have yet been established for group studies. However, it is safe to say that four assessment sessions over a 4-week period is a minimum requirement.

Control groups. The arguments given

previously not only suggest the use of extended baseline assessment of blood pressure but also the inclusion of a waiting list control group. Type, length, and number of assessment sessions should be identical for all groups throughout the baseline and training or control period. A further reason for the inclusion of a control group is that the mere fact of being attended to, the fact that something is being done about their prob-

Table 1
Psychological Control of Essential Hypertension: Biofeedback Studies

n	Concurrent pharmacological treatment	Baseline	Training procedure
		Benson et al. (1971)	
7	6 subjects on stable dosage of hypotensive medication	Average of 11 sessions over 2 weeks (sessions run until BP stabilized)	Systolic BP feedback: Constant cuff method, contingent slide projection, and monetary rewards
		Elder et al. (1973)	
18	Several subjects on stable (?) dosage of various CNS depressants	1 session of 20 BP determinations	1. Diastolic BP feedback ($n = 6$): Visual signal every 2 min. contingent on diastolic BP reduction 2. Diastolic BP feedback, contingent verbal approval ($n = 6$) 3. Control group ($n = 6$): Asked to relax and lower BP, no feedback
		Elder & Eustis (1975)	
22	20 subjects on stable (?) dosage of psychotropic or hypotensive medication	No baseline period, pretrial baseline only	Diastolic BP feedback: Visual feedback (green light for changes below, red light for no change or increase above basal pressure) at 1-min. intervals, verbal reinforcement
		Kristt & Engel (1975)	
5	All subjects on stable dosage of hypotensive medication	No baseline period, pretrial baseline only	Systolic BP feedback: Constant cuff method, display of cumulative performance scores; Week 1: Raise systolic BP; Week 2: Lower systolic BP; Week 3: Alternately lower, raise, lower BP within single session

lem, may bring considerable relief to subjects, with subsequent falls in blood pressure over time. Only 10 out of the 21 studies reported here included a control condition, but in 3 of these (Goldman et al., 1975; Patel, 1975a; Stone & DeLeo, 1976) subjects were not allocated in random fashion. In addition, several of the control conditions were inadequate. In some studies, especially those investigating within-session changes,

Table 1 (*continued*)

Frequency and duration of training (and follow-up)	BP changes pre/posttest and follow-up	Statistical analysis	Control
	Benson et al. (1971)		
Average of 22 45-min. sesssions on consecutive days (sessions run until no reduction for 5 sessions)	Within-session decrease: −17 mmHg systolic, 5 out of 7 subjects responded	Significant within-session reduction (ANOVA)	Extensive baseline; no control groups; no across-sessions measures; no follow-up
	Elder et al. (1973)		
7 40-min. sessions over 3 days, 1-week follow-up	1. 7% reduction in diastolic BP by Sessions 7 and 8 2. 20% reduction in diastolic BP in Sessions 3–8 3. No significant changes in BP	Group 2 significantly superior to Groups 1 and 3 in sessions 3–8; Group 1 superior to 3 in sessions 8 and 9 (ANOVA); reductions maintained at follow-up, (n = 11) no statistical tests	Control group; subjects started on salt-free diet 3 days prior to training; no extended baseline and follow-up; selective reporting and lack of detail in results section
	Elder & Eustis (1975)		
Spaced sessions (n = 19): 8 sessions of 20 trials each over 7 weeks, 1-month follow-up Massed sessions (n = 4): 10 sessions over 12 days, no follow-up	% difference from basal pressure presented in graphical form only Within-session reduction: Approximately 5% systolic + diastolic (somewhat larger for massed sessions) Follow-up: Within-session reductions approximately 3% systolic and diastolic	Significant difference between first and second half of training sessions (Mann-Whitney U)	No properly verified diagnosis of essential hypertension; no control groups; data based on % difference from basal pressure, which was assessed only once in first training session; data reported in confusing way
	Kristt & Engel (1975)		
42 sessions of 3 blocks of 10 trials each over 3 weeks, 3-month follow-up	Subjects reliably increased and decreased systolic BP, ability maintained at follow-up Pretest follow-up BP reductions as recorded by 4 subjects at home: −18.2 mmHg systolic −7.5 mmHg diastolic	Trend analysis statistics significant for all 3 conditions No statistical tests reported	No control groups; no clinic assessment of pre-follow-up changes in BP reported

		Kleinman et al. (1977)	
8	None	3 2-hour clinic sessions over 3 weeks, BP recording by subjects 5 times daily over 2 weeks	Systolic BP feedback: Constant cuff method

Note. BP = blood pressure; CNS = central nervous system; ANOVA = analysis of variance. Reported

control subjects either did not sit for the same length of time as subjects in the training conditions (Deabler et al., 1973; Shoemaker & Tasto, 1975) or attended fewer sessions than the training group (Goldman et al., 1975; Taylor et al., 1977).

As in all forms of psychological intervention, nonspecific treatment factors undoubtedly play an important role in biofeedback and relaxation/meditation training. Various experiments (e.g., Goldring, Chasis, Schreiner, & Smith, 1956; Grenfell, Briggs, & Holland, 1964) have suggested that placebo treatments can have dramatic effects on blood pressure, although these results were confounded by the fact that treatment coincided with the beginning of longer hospitalization periods. In the present review only two studies included controls for nonspecific treatment effects. Taylor et al. (1977) used nondirective discussion groups in which subjects monitored and explored life's tensions and discussed solutions. Frankel, Patel, Horowitz, Friedwald, & Gaardner (1978) compared noncontingent diastolic blood pressure feedback with contingent feedback and also used a waiting list control group. In both studies no significant blood pressure reductions were observed in the control groups. Unfortunately, it was not determined whether the nonspecific treatment control conditions were as credible as the actual training procedures. As Kazdin and Wilcoxon (1976) pointed out, subjects who are exposed to control conditions that are less credible than the treatment condition are less likely to expect improvement. Expectancy of improvement is one of the most powerful nonspecific treatment factors, and it can be hypothesized that the apparent beneficial

1. 9 2-hour sessions of 30 trials each over 9 weeks 2. 3 2-hour sessions over 3 weeks	1. Within-sessions: −7 mmHg systolic Across-sessions: −6 mmHg systolic −15 mmHg diastolic 2. Within-session: −1 mmHg systolic Across-sessions: 4 mmHg systolic −4 mmHg diastolic	Within-session: Reductions significant for Group 1 only (ANOVA) Across-sessions: Changes significant for Group 1 on diastolic BP only (ANOVA)	Groups 1 and 2 had different pretraining BP, unsophisticated BP measurement; no random allocation; different number of sessions given to Groups 1 and 2; no follow-up
	Kleinman et al. (1977)		
9 2-hour sessions of 25–30 trials each over 9 weeks; follow-up BP recorded by subjects up to 4 months	Within-session: a. Control session: −.5 mmHg systolic −1.6 mmHg diastolic b. Feedback session: −4 mmHg systolic −4 mmHg diastolic Across-sessions (as recorded by subjects): −8 mmHg systolic −9 mmHg diastolic Maintenance of BP reduction at follow-up (n = 3)	Within-session: Reduction significant for Group b only on systolic BP (t test) Across-sessions: Reductions significant for systolic and diastolic BP (t test) No statistical test on follow-up data	No control groups; no report of laboratory-recorded across-sessions changes

blood pressure changes refer to across-session changes unless otherwise specified.

effect of a particular treatment may simply be due to this effect (Borkovec & Nau, 1972). For future research it is therefore important not only to include nonspecific control groups but also to ascertain that there is equal expectancy of improvement across conditions (Steinmark & Borkovec, 1974).

Length of training and follow-up period. A further drawback of many of the studies is that they use short training periods of sometimes not more than 1 week (Deabler et al., 1973; Elder et al., 1973) or use only a small number of training sessions. In studies reporting negative or statistically significant but clinically irrelevant results, it is therefore difficult to evaluate whether the technique was inefficient or the training was not intensive enough. In addition, follow-up assessment was frequently omitted or covered too short a period of time. The long-term durability of training effects is clearly a crucial issue that needs much more careful attention in future research. A minimum training period of 3 months and a follow-up period of 1 year is therefore suggested. Even longer follow-ups are necessary to determine whether and how the psychological control of essential hypertension effects morbidity and mortality.

Home practice and life-style changes. Sixteen out of 21 researchers asked their subjects to practice their respective techniques daily at home. Often, however, details of home practice procedures were not given, and only one researcher (Frankel et al., 1978) reported on actual compliance rates. Despite this lack of systematic data, there is evidence which suggests that regular daily home practice is crucial in achieving

and maintaining reductions in blood pressure. The commitment involved is similar to if not greater than that in pharmacological treatment, in which medication is usually taken on a regular daily basis and is a lifelong commitment. It is recommended that home

practice frequencies be recorded and reported as data in all future research.

It is worth adding that subjects who regularly practice a relaxation/meditation technique may as a consequence undertake changes in their life-style. To date, such

potential changes (e.g., diet, exercise, smoking, alcohol consumption, use of drugs) have not been monitored but may well make some contribution to the reduction of blood pressure.

Assessment and reporting of training effects. The quality of studies was highly variable both in terms of their assessment procedures and the completeness of reports. In this context it is important to point out the difference between within-session and across-sessions measures. Within-session measures are typically taken either while the person is practicing a self-regulatory technique or at the end of the training session when blood pressure is likely to be lowest. To determine whether results achieved under training conditions have generalized to nontraining conditions, blood pressure has to be measured and reported across sessions, that is, independent of or immediately prior to the self-regulatory practice. All blood pressure values presented in Tables 1–4 were based on across-sessions measures unless otherwise specified.

In several studies, baseline blood pressure values were compared with those at the end of the last training session (Elder & Eustis, 1975; Elder et al., 1973; Goldman et al., 1975; Patel, 1973; Walsh et al., 1977). This of course, creates biased results that are likely to reflect both the effects of adaptation and resting and those of specific training.

In other studies, across-sessions measures were simply not reported (Benson et al., 1971; Deabler et al., 1973; Elder et al., 1973; Elder & Eustis, 1975; Kleinman et al., 1977), although these data must have been taken at least in the biofeedback studies, if only for calibration purposes. Finally, some experimenters relied on blood pressure values as recorded by the subjects themselves without reporting any assessment of relia-

bility or comparative laboratory results (Kleinman, Goldman, Snow & Korol, 1977; Kristt & Engel, 1975; Hager & Surwit, Note 3).

For future research the simultaneous use and detailed reporting of within-session and across-sessions measures are strongly recommended. Temporary blood pressure reductions that occur only during training are of limited clinical importance. On the other hand, exclusive reliance on across-sessions measures prohibits the acquisition of information on the short-term effectiveness of a given technique. The concomitant use of both measures is particularly relevant in understanding failure to respond to training. Regarding the quality of blood pressure recording, researchers are urged to employ independent observers and to use either automated recording devices (Krausman, 1975; Tursky, 1974) or the random-zero-sphygmomanometer (Wright & Dore, 1970).

Generalization of training effects. The generalization of training effects is an important issue that has received much discussion but has not yet been systematically studied. Although several experimenters used different settings for training and assessment (Benson, Rosner, Marzetta, & Klemchuck, 1974a, 1974b; Blackwell et al., 1976; Frankel et al., 1978; Pollack, Weber, Case, & Laragh, 1977; Taylor et al., 1977), in the majority of studies reviewed here, training effects were assessed in the same environment in which training took place. It can therefore be argued that training effects were specific to the particular experimenter and to the laboratory setting in which subjects were trained and that in some cases the obtained changes would not have been maintained in a nonlaboratory environment. So far this latter issue has not been scientifically investigated.

Further, all training and assessments have

been conducted in a sitting or recumbent position in an undemanding environment under conditions of drastically reduced external stimulation. Although blood pressure taken under standard resting conditions gives us useful information, this type of data tells us nothing about whether training effects have generalized to the person's everyday environment or not. Blood pressure changes, especially the speed and magnitude of elevations and their rate of recovery, are also of importance. It is hoped that this crucial issue of generalization of training effects will be approached soon. It requires the use of portable monitoring equipment, which is now available (Littler, Honour, Pugsley, & Sleight, 1975; Littler, Honour, Sleight, & Stott, 1972). One perhaps more

practical alternative is to expose subjects to standard stressors under laboratory conditions. To date only one investigator (Patel, 1975b) has studied the effects of biofeedback-aided relaxation/meditation training on blood pressure response and recovery. In a preliminary experiment, 32 essential hypertensives were randomly assigned to either a training or a waiting list control condition. Maximum blood pressure elevations in response to a "stressful" exercise and cold pressor test and the time taken for recovery were assessed before and after 6 weeks of training. Relaxation training resulted in significant reductions in systolic and diastolic blood pressure elevations and recovery time for both tests. Control subjects did not display any significant reductions on either

	Walsh et al. (1977)		
5 1-hour sessions over 5 weeks, 5 sessions of 7 3-min. trials each, information on pre/post session BP Training period not reported, 5 1½-hour sessions, 3-month and 1-year follow-up	Phase 1 No details given; graphical description only Phase 2 Slight increases in BP (no details given) Groups 1 and 2 (combined) reduced BP from 146/94 mmHg at beginning of Phase 1 to 134/87 mmHg at end of Phase 2 3-month follow-up: Subjects from Group 1 had lower systolic BP 1-year follow-up: No between-groups difference	Within-session: Group 2 superior to Groups 1 on diastolic BP (ANOVA) Across-sessions: No significant between-groups difference (ANOVA) No statistical analysis reported Significant difference (t test) No statistical analysis reported	No control group; incomplete reporting; errors due to technical problem?

measure. With the exception of systolic blood pressure rises in the exercise test, differences were significant for all between-groups comparisons. Despite some methodological shortcomings, these results are highly relevant and worth replicating.

Discussion of Results

In the following section, the effectiveness of the various techniques that have been applied to the control of essential hypertension is critically evaluated. Each of the three approaches presented in Tables 1–3, namely, blood pressure biofeedback, relaxation/meditation, and biofeedback combined with relaxation/meditation, is discussed separately and highlighted by a brief description of the most noteworthy studies. Finally, blood pressure and relaxation/meditation training are compared (Table 4), and explanations for differences in outcome are proposed.

Blood pressure biofeedback. Ten studies investigating blood pressure biofeedback in the treatment of essential hypertension are presented in Tables 1 and 4. In general, results support findings of studies using normotensives as subjects. Under laboratory conditions various blood pressure feedback techniques produced significant across-sessions reductions in systolic blood pressure (ranging from 6–18 mmHg) and in diastolic blood pressure (ranging from 8–15 mmHg). Two studies stand out: Benson et al. (1971) and Kristt and Engel (1975).

Benson et al. (1971) trained seven subjects using the constant cuff technique. Baseline assessment and training sessions were individualized, and training continued until each subject showed no further reductions in systolic blood pressure in 5 consecutive sessions. The average number of training sessions was 22 (range = 8–34) over a 4½-week period, and average within-session decreases in systolic blood pressure were 17 mmHg. Although this study did not include a control group and lacks across-sessions and follow-up data, it is one of the best controlled in the field.

Kristt and Engel (1975) taught five subjects to reliably increase and decrease systolic blood pressure within sessions. Again the constant cuff technique was used. Data were presented in graphical form only but suggested average increases and decreases in systolic pressure of 10–15 mmHg. Training was conducted in 42 sessions during a 3-week hospital stay. After discharge from the hospital, subjects continued to practice lowering systolic blood pressure at home on a daily basis. They did this by inflating a standard cuff to their average blood pressures and making Korotkoff sounds disappear while cuff pressure was maintained. Cuff pressure was then adjusted to the new lower pressure, and the procedure was repeated. After 3 months of home training, blood pressure as measured by subjects in their home, had decreased 18 mmHg systolic and 8 mmHg diastolic from pretreatment baseline. For several reasons these results have to be interpreted cautiously: (a) Subjects had shown no across-sessions reductions in the laboratory; (b) blood pressure taken by subjects at home was not checked against blood pressure taken by an independent observer; (c) there was no control group, and the number of subjects at follow-up was too small (n = 4); and (d) there is no way to determine whether the simulated blood pressure control procedure was instrumental in producing these reductions or whether other factors, such as taking time out to practice and relax, were the crucial components.

Two studies (Shoemaker & Tasto, 1975; Surwit et al., 1978) failed to produce any decreases in blood pressure. In both cases the feedback techniques that were used appear inappropriate. Shoemaker and Tasto applied a noncontinuous proportional feedback technique in which once every 90 sec subjects were shown their systolic and diastolic blood pressure on a chart recorder and asked to reduce both. This probably was too complex a task. In the study by Surwit et al., which used the constant cuff technique, subjects received binary feedback for simultaneous reductions in blood pressure and heart rate; that is, feedback for a "correct" response was only given when decreases in blood pressure coincided with decreases in heart rate. As the authors themselves pointed out, this procedure was

probably ineffective because subjects had normal heart rates to start with.

With regard to which blood pressure feedback technique is most effective, no conclusive answer is possible. Comparative studies with essential hypertensives have not yet been conducted. But there is evidence which suggests that the constant cuff technique is the most promising one, whereas the pulse wave velocity technique still needs further testing. However, at present we have no convincing indication that essential hypertensives can achieve clinically relevant and persistent blood pressure reductions through blood pressure feedback training. Successful blood pressure control may require more intensive individualized training (e.g., Benson et al., 1971) and continued home practice (Kristt & Engel, 1975). Although home practice appears to be crucial for the maintenance of blood pressure reductions in relaxation/meditation training, the role of home practice and its relaxation components in blood pressure feedback training is far from clear (Tarler-Benlolo, 1978).

Relaxation/meditation. The overall methodological quality of relaxation/meditation studies is better than that of blood pressure biofeedback studies. Subject samples are larger, and across-sessions measures and adequate follow-up or extended training periods of approximately 6 months are reported in all but one study (Deabler et al., 1973). Blood pressure reductions across sessions were in the range of 7–14 mmHg for systolic and of 4–10 mmHg for diastolic blood pressure. Two studies are worth describing in some detail.

Stone and DeLeo (1976) compared 14 subjects who were trained in breath meditation with a small control group ($n = 5$). Training consisted only of five sessions, but subjects were asked to practice regularly at home. After 6 months of practice, systolic and diastolic blood pressure in the supine position were reduced by 15 and 10 mmHg, respectively, whereas blood pressure in the control group had slightly increased (+1/+2 mmHg). Plasma dopamine β-hydroxylase levels were also found to be significantly reduced and to correlate with falls in blood pressure. Dopamine β-hydroxylase is an enzyme that converts dopamine to norepinephrine and has been suggested to be an indicator of sympathetic nervous system activity. The fact that the experimental and the control group were of unequal size and that subjects were not randomly allocated to groups necessitates caution in interpretation. In addition, pretreatment blood pressures were in the borderline hypertensive range, and subjects were much younger than in all other studies reviewed here.

In an exceptionally well-controlled study, Taylor et al. (1977) compared three groups of subjects on medication ($n = 31$) over an 8-week period. The first group received relaxation training, the second, nonspecific treatment, and the third, no treatment at all. The relaxation technique consisted of progressive muscle relaxation, the imagination of pleasant scenes, and self-monitoring. The relaxation group achieved the greatest decreases (−14 mmHg systolic, −5 mmHg diastolic), but only in the case of systolic blood pressure were they statistically significant. At a 3-month follow-up assessment, relaxation subjects had generally maintained their reductions (−12/−6 mmHg) but did not differ significantly from the other two groups, which had by then displayed further small decreases in blood pressure (−7/−2 mmHg for the medication-only and −4/−4 mmHg for the nonspecific treatment group).

Several single-case studies, which so far have not been mentioned in this review, have also investigated the effects of progressive relaxation and the modification thereof on essential hypertension (Beiman, Graham, & Ciminero, 1978; Bloom & Cantrell, 1978; Brady, Luborsky, & Kron, 1974; Graham, Beiman, & Ciminero, 1977). The report by Brady et al. (1974) deserves special mention because it used A-B-A and A-B-A-B single-case designs that have otherwise not been used in clinical studies of essential hypertension. (For a discussion of single-case designs in clinical biofeedback research, see Barlow, Blanchard, Hayes, & Epstein, 1977.) After 2–4 weeks of daily half-hour blood pressure assessment sessions (Baseline 1), the three subjects in the Brady et al. study received between 19 and 25 half-hour training sessions of metronome-conditioned relaxation training

(Training 1) over 4 weeks. This was followed by another 4 weeks of daily blood pressure checks without any further training practice (Baseline 2). One subject showed no change, whereas the other two showed significant decreases in diastolic blood pressure (of 3 mmHg and 6 mmHg, respectively) during Training 1, and significant increases in diastolic blood pressure (of 5 mmHg and 8 mmHg, respectively) in Baseline 2. One subject resumed relaxation after Baseline 2, which resulted in a drop in diastolic blood pressure of 13 mmHg. Systolic blood pressure was not reported.

Different relaxation and meditation techniques have not yet been compared with each other; therefore, at this stage, little can be said about which technique is likely to be more effective. Of the three techniques that have been investigated, progressive relaxation and breadth meditation appear to have produced slightly larger decreases in blood pressure than TM. Of the seven studies reviewed in Table 2, none of the four TM studies included a control group.

Mixed studies. Four studies that investigated a combination of various biofeedback and relaxation/meditation techniques in the psychological control of essential hypertension are reviewed in Table 3. The work by Patel and North (1975) has shown the most impressive results of all studies discussed in this review. Training consisted of a combination of educational programs, rhythmic slow breathing, muscular relaxation, meditation, GSR and EMG feedback, and various self-control procedures for coping with everyday difficult situations. Reductions in mean values after a 6-week training and a 3-month follow-up period were 26 mmHg systolic and 15 mmHg diastolic. The 17 control subjects who attended the same number of sessions but simply rested and relaxed on their own also achieved significant reductions of 9 mmHg systolic and 4 mmHg diastolic. However, the difference between the two groups was highly significant. The results are particularly convincing in that the investigators used a half-crossover design in which control subjects later underwent the full training procedure and as a result reduced their blood pressure by 28 mmHg systolic and 16 mmHg diastolic.

Frankel et al. (1978) used a similar training package consisting of diastolic blood pressure feedback (constant cuff technique), EMG feedback, autogenic training, and progressive relaxation and compared it with a group receiving noncontingent diastolic blood pressure feedback and with a waiting list control group. After 4 months of training, no significant blood pressure reductions were found in any of the groups. The reasons for these diametrically opposed outcomes are difficult to assess. Because of the simultaneous application of several training procedures, it is impossible to isolate the active ingredients in these training packages. However, training appeared to be more intensive and comprehensive in the Patel study, and baseline systolic blood pressure for the whole sample was also considerably higher (168/100 vs. 153/99).

Blood pressure biofeedback and relaxation/meditation compared. The four studies comparing blood pressure biofeedback and relaxation/meditation techniques (Table 4) have not helped much in assessing the possible differential effectiveness of these techniques. Two of the studies slightly favor progressive relaxation over noncontinuous, proportional (Shoemaker & Tasto, 1975), and pulse wave velocity feedback (Walsh et al., 1977). The other two studies both find breath meditation equally ineffective as a portable constant cuff technique (Hager & Surwit, Note 3) and as a constant cuff technique for simultaneous reductions in systolic blood pressure and heart rate (Surwit et al., 1978). Unfortunately, the studies of Walsh et al. and Hager and Surwit are of poor methodological quality, and the studies by Shoemaker and Tasto and Surwit et al. probably used, as previously discussed, inappropriate blood pressure feedback techniques. Finally, a recent experiment with normotensives (Steptoe, 1978), which compared pulse wave velocity feedback and breath meditation, also produced equivocal results.

In drawing general conclusions regarding the comparative effectiveness of relaxation/meditation and blood pressure feedback techniques, we are therefore restricted to the non-

comparative studies previously reviewed. Although experimental evidence is still somewhat weak, it is safe to say that in contrast to blood pressure biofeedback training, relaxation/meditation training has produced small but significant reductions in blood pressure with essential hypertensives. These reductions have been shown to persist for up to 6 months and to generalize to environments other than those in which training was conducted (e.g., Frankel et al., 1978). To account for the greater effectiveness of relaxation/meditation approaches, the following explanations are suggested.

1. Integrated physiological pattern versus specificity of blood pressure control. More effective, rapid, and persistent blood pressure control is likely to be attained if the self-regulation of blood pressure is accompanied by compatible changes in other physiological parameters such as heart rate, respiratory rate, muscle relaxation, and so on. Relaxation/meditation techniques are assumed to be more effective because they elicit such an integrated physiological pattern (Schwartz, 1976), whereas blood pressure feedback training may only affect blood pressure without concomitant changes in heart rate and other physiological parameters.

2. Home practice. As a rule relaxation/meditation techniques are taught in five to eight sessions, but the major part of training actually takes place in the subject's home environment in which he or she is advised to practice daily. These home practice sessions, which are usually not part of blood pressure biofeedback training, may be an important factor in explaining the superiority of relaxation/meditation approaches. It is interesting to note that the only blood pressure feedback study that showed blood pressure reductions to persist at a 3-month follow-up was also one of the few studies in which subjects practiced reducing blood pressure at home on a daily basis (Kristt & Engel, 1975).

3. Patient involvement. The role of patient involvement in the psychological control of essential hypertension has so far not been systematically studied. But an unpublished report by Sherman and Gaardner (Note 4) suggests that this factor may affect treatment outcome. They rated all available studies using biofeedback and relaxation/meditation techniques according to their treatment effectiveness and the degree of patient involvement. They found a significant correlation indicating that the more patients were involved, the higher was the treatment effectiveness. Patient involvement was defined by the number of training sessions, the intensity of home practice and recording, awareness of unwanted stress, expectancy of improvement elicited by training instructions, and the number of techniques used. Although Sherman and Gaardner did not differentiate between blood pressure feedback and relaxation/meditation training, it appears that the latter would receive higher ratings on patient involvement than the former.

Several other differences between blood pressure feedback and relaxation/meditation training with regard to patient involvement are worth mentioning here. In relaxation/meditation training subjects are taught individually or in groups by an instructor who is likely to respond to individual questions, who gives encouragement, and who may serve as a model. In blood pressure biofeedback training, the patient–instructor contact is probably much shorter and less personal than in relaxation/meditation training. It is mainly the "machine" that is in the role of the instructor. Training is also likely to take place in a more technical, controlled, and alien environment. In addition, repeated cuff inflations and the maintenance of cuff pressure may be unpleasant and distracting for some subjects.

Finally, relaxation/meditation approaches have the advantage of also positively affecting stress-related complaints such as insomnia (e.g., Borkovec & Hennings, 1978) and other clinical problems (Shapiro & Giber, 1978) and of increasing self-reported measures of health, performance, and well-being (Peters, Benson, & Porter, 1977). Subjects experiencing such changes may well become highly motivated to continue home practice on a regular basis.

If techniques of relaxation/meditation are combined with self-control procedures and with EMG and GSR feedback training, blood pressure effects are likely to be even larger (Patel & North, 1975). The combined use of

diastolic blood pressure feedback training and other techniques for relaxation has produced negative results (Frankel et al., 1978). On the other hand, Fey and Lindholm (1978), who worked with normotensive subjects, found that blood pressure feedback (constant cuff technique), when combined with progressive relaxation training, produced larger within-session reductions in systolic blood pressure than progressive relaxation alone. However, in a follow-up session, when no feedback was provided, the two groups no longer differed. Feedback training then appears to improve or facilitate within-session control of blood pressure but tends to lose its effect when it is withdrawn.

Issues of Experimental Design

All of the studies that have been reviewed in Tables 1–4 are outcome studies of either between-groups or single-group designs, except for one study of single-case experiments (Benson et al., 1971). The inadequacies of the single-group design are obvious and need no further mention here. Accordingly, the discussion concentrates on the pros and cons of between-groups versus single-case experimental designs. Two major advantages of the between-groups comparison design stand out. (a) It allows the investigation of the comparative effectiveness of two or more training procedures, and (b) results have a wider application. In contrast, generalizations based on single-case experiments have to be made cautiously.

Large individual differences in response to relaxation/meditation and biofeedback training have been reported by many researchers. Single-case experiments have the great advantage of treating intrasubject and intersubject variability not as error but as information (Barlow et al., 1977). One consequence of intersubject variability is of particular concern in group designs, as Hersen and Barlow (1976) have pointed out:

> When broad divergence . . . occurs among clients in response to an intervention, statistical treatments will average out the clinical effects along with changes due to unwanted sources of variability. In fact, this type of intersubject variability is the rule rather than the exception. (pp. 37–38)

Group designs in general are based on the assumption that all subjects in a given sample have homogeneous characteristics. In the case of clinical samples, homogeneity of disorder and etiology is also assumed. However, since it is generally accepted that essential hypertension is a multicausal disorder, it is likely that within each group there are subsamples that respond differently to training. One way of overcoming this difficulty is to apply more stringent sampling criteria. Another alternative is to match subjects on certain variables. But unfortunately, at present, the relevant matching variables are simply not known. Group designs also imply that a standardized method of intervention is appropriate for all subjects. But because of the heterogeneity of etiology in essential hypertension, such an assumption is clearly inappropriate. Yet training procedures used in group designs must be designed in such a way that they are generally suitable for all subjects, and once the experiment is under way, they cannot be adjusted to the individual needs of the subject. It is then not surprising that many group outcome studies yield statistically significant but clinically irrelevant results. In contrast, single-case experiments allow for training procedures to be tailored to the specific needs of each person and permit the testing of specific components of a given training procedure.

For future research the use of both types of designs is recommended. Single-case experiments would prove particularly valuable in deciding which training procedure is likely to achieve the best results with which type of subject. This could be followed up by multifactorial between-groups studies in which one or more training procedures would be compared with different subject samples (e.g., comparing the effects of progressive relaxation and breath meditation on essential hypertensives with high versus low pretest frontalis EMG levels). Further, between-groups studies can be improved by not only gathering pretest, posttest, and follow-up data but also by repeating measurements during the training period. Such a repeated measures design (Kiesler, 1971) would allow both outcome and process information.

Suggestions for a Comprehensive Approach to Assessment and Training

It will have become clear from this review that so far, psychological approaches have had only limited success in controlling essential hypertension. One reason for this may be that the commonly invoked psychophysiological model of essential hypertension is too narrow and that assessment and treatment based on this model are too simplistic. Most studies attempting to control elevated blood pressure through psychological techniques have aimed at counteracting or reducing the sympathetic nervous system activity that is assumed to play a central role in essential hypertension. The question of what actually causes sympathetic arousal in the first place is rarely asked. It is hypothesized here that to a considerable degree, the person's sympathetic arousal reflects idiosyncratic ways of perceiving, appraising, and interacting with his or her environment. It could therefore prove useful not only to measure blood pressure and other related physiological variables but also to measure cognitive appraisal and coping patterns in response to environmental demand. Assessment could take place in the laboratory applying standard stressors (Richter-Heinrich, Knust, Müller, Schmidt, & Sprung, 1975) or in the person's real-life environment (e.g., at the person's work place). The latter is a practicable proposition because the necessary technology is now available (Littler et al., 1975).

Such comprehensive assessment would allow the determination of which situations and events the person responds to with blood pressure elevations and whether they are mediated by dysfunctional patterns of thinking, emoting, and behaving. A more comprehensive approach to training would make use of specific behavioral techniques, cognitive restructuring (Goldfried, 1977), and stress management techniques such as anxiety management (Bloom & Cantrell, 1978) and stress inoculation training (Meichenbaum, 1977). It is hoped that future research will examine whether these techniques that aim at systematically teaching active coping skills produce greater blood pressure effects than the more passive techniques of blood pressure control described in this review.

Conclusion

In conclusion, psychological approaches to the self-regulation of high blood pressure are a promising *adjunct* to pharmacological treatment, and under the supervision of a physician, may allow the gradual reduction of medication requirements as the patient becomes more proficient in his or her respective technique (Patel & North, 1975). However, without more large-scale clinical trials with sound methodology, an unqualified acceptance of these techniques as an *alternative* to pharmacological treatment is not justified. To date, few studies have resulted in blood pressure reductions that are clinically relevant by virtue of either their magnitude or duration. It has been clearly shown that substantial blood pressure reductions can be achieved under laboratory conditions and that after periods of consistent relaxation/meditation practice, these changes are maintained under resting conditions without prior practice. But it has not yet been demonstrated whether training reduces blood pressure in the person's real-life environment. The active therapeutic ingredients of the various techniques have not yet been satisfactorily established, and only two studies have used nonspecific treatment control procedures.

It is unlikely that any one single technique will be suitable for all subjects, but rather a variety of approaches is necessary to deal effectively with individual differences in physiological and psychological responding. It is important that research should concentrate on differential diagnosis, with the aim of establishing criteria for choosing the most appropriate intervention techniques. Such research would also help to stimulate the development of new techniques or to suggest new combinations of existing ones.

A wide application of psychological approaches to the prevention and control of essential hypertension is unlikely in the immediate future. On the one hand, much more needs to be known about which tech-

nique or combination of techniques works best with whom. On the other hand, a wide application of these techniques requires a major shift in attitude of the general population and of the medical and health professions. The majority of people may prefer the easier course of medication rather than the more demanding process of training and daily practice. This attitude may not so much reflect a lack of willingness to take responsibility for one's own health as a lack of awareness of how personal habits effect it and how they may be changed.

It is hoped that psychologists will play an increasingly important role in heightening general awareness and in researching and teaching the skills conducive to health and the prevention of disease.

Cognitive Behavior Modification: Misconceptions and Premature Evacuation

Michael J. Mahoney and Alan E. Kazdin
The Pennsylvania State University

Ledwidge's recent implication that cognitive behavior modification is "a step in the wrong direction" is examined and evaluated. Misconceptions about the alleged differences between cognitive and behavior therapists are noted, with particular emphasis on metaphysical dualism and dichotomous categorization. The classification of therapists according to the techniques that they employ is also questioned. It is argued that procedural overlap is common across schools of therapy and that categorical distinctions—when they are possible—are more likely to be valid when they are based on theoretical assumptions rather than on therapeutic techniques. The argument that behavior therapists rely almost exclusively on nonverbal means is challenged, as is the assertion that cognitively oriented therapists "rely chiefly on speech as the instrument of change." Finally, it is argued that Ledwidge's cautions about the continuing pursuit of cognitive-behavioral techniques are themselves premature and contrary to the commitment to empirical evaluation shared by both cognitive and less cognitive behavior therapists.

It is perhaps not surprising that the emergence of cognition in behavioral quarters has stimulated such strong and vituperative reactions. Within the last 2 years alone, there have been almost a dozen articles and papers attacking the "mentalistic" resurrection of cognitive processes in behavior modification (Goldiamond, 1976; Observer, 1977, 1978; Rachlin, 1977a, 1977b; Skinner, 1977; Wolpe, 1976a, 1976b, 1978). The sentiment of most of these writings is aptly summarized in a recent *Psychological Record* editorial (Observer, 1978):

> Cognitivism constitutes a counter-revolution to the behavioristic revoluton that promised to promote psychology to a scientific status . . . . (p. 157)

> Students of scientific psychology cannot but deplore the regressive tendencies of cognitive psychology. (p. 159)

In his recent evaluation of cognitive behavior modification, Ledwidge (1978) sounds a similar alarm regarding the apparent trend toward cognitive theorization in behavior modification:

> A wholesale conversion to cognitive methods on insufficient evidence could rob behavior therapy of its distinctiveness and lead to the abandonment of the more traditional behavioral techniques, the success of which have afforded (behavior) therapy the reputation it enjoys today. (p. 354)

After a sporadic review of the available literature, Ledwidge draws a mixture of conclusions that seem only tangentially related to extant evidence. It is the purpose of this brief article to point out some of the misconceptions in Ledwidge's review and to isolate some of the pivotal issues that seem to be developing along the interface of cognitive psychology and behavior modification.

Dualism and Dichotomy

Two of the most persistent myths that surround the developing interface are the notions that (a) cognitivism necessitates mentalism and that (b) a therapist (or the

Requests for reprints should be sent to Michael J. Mahoney, Department of Psychology, The Pennsylvania State University, 417 Bruce V. Moore Building, University Park, Pennsylvania 16802.

orist) is either exclusively cognitive or behavioral (but never the twain shall meet). The first assumption is apparent in Skinner's (1974) recent responses to the growing interest in cognitive psychology. He uses the terms "cognitive psychologist" and "mentalist" interchangeably:

> By attempting to move human behavior into a world of nonphysical dimensions, mentalistic or cognitive psychologists have cast the basic issues in insoluble forms. They have also probably cost us much useful evidence . . . . (p. 118)

This same sentiment is reiterated by Ledwidge (1978) when he states that "the present controversy is, of course, just another round in the centuries old mind–body debate" (p. 360). What is interesting is that the metaphysical issue of a nonphysical mind does not appear to differentiate groups that have been traditionally labeled as cognitive and behavioristic. In a recent survey involving 42 of the most eminent living contributors to behavior therapy and cognitive behavior modification, no significant differences in belief in the existence of a "mind" emerged (Mahoney, in press). There were also no differences in the extent to which these two groups emphasized the importance of experimental rigor in theory evaluation.

The second myth is more subtly defended by Ledwidge's (1978) insistence on the differentiation of cognitive and behavioral therapies—a distinction that he defends on the grounds that (a) cognitive-behavioral techniques do not attempt to directly modify behaviors and that (b) should these new techniques fail to improve on the therapeutic power of behavior therapy, they will "unjustifiably detract from the good reputation that behavior modification enjoys today" (p. 372). Interestingly, Ledwidge concedes that all forms of therapy involve some form of cognition:

> All forms of therapy, including medical treatment, are cognitive to the extent that the therapist must convince the client to cooperate in the suggested procedure before therapy can begin. In this trivial sense all . . . therapies . . . are cognitive. (p. 357)

One might take issue with the assumption that compliance and trust are "trivial" issues, but the basic point is that clients are presumed to think. What is apparently overlooked is the equally salient observation that therapists behave. At some level of analysis, all forms of psychotherapy involve behaviors on the part of a therapist that are intended to produce changes in the ongoing experiences of a client. Thus, one might also argue that all therapies are simultaneously cognitive and behavioral.

A more compelling illustration of this point is offered by Bandura's (1977a) timely emphasis on the distinction between procedures and processes. According to Bandura—and many other persons labeled "cognitive behavior modifiers"—the processes that govern human adjustment (and maladjustment) are cognitive in nature. (i.e., They involve attentional processes, aspects of information storage and retrieval, etc.) However, in almost comic irony, it now appears that behavioral procedures may be among the most powerful methods for activating those cognitive processes. Thus, if any clear distinction can be drawn, the major difference between cognitive and less cognitive behavior modifiers does not lie in their therapeutic procedures so much as in their rationale and selection of a given procedure in an individual case. The more cognitively oriented therapist is inclined to employ a behavioral procedure appropriate to the "cognitive restructuring" presumed to be required.

Misconceptions About Cognitive Therapy

This confusion regarding process and procedure is most apparent in discussions about the modification of verbal behavior. In an attempt to lump all nonbehavioral approaches into a broad category of psychotherapy, Ledwidge (1978) appears to lament the recognition of thoughts as therapeutic targets in behavior therapy:

> Slowly, but surely, over the years, behavior theory has become more cognitive. Cognitions, relabeled self-statements, are classed as behaviors. Whereas changing a person's mind was, and still is, considered psychotherapy, changing a person's self-statements passes for behavior therapy. (p. 354)

It is, of course, a special form of therapy, and Ledwidge prefers to call it cognitive therapy rather than cognitive behavior modification. The label is perhaps less important than the accurate assumption that "cognitive change (is) the active ingredient in treatment" (p. 356). Much less accurate, however, is the assertion that

> whereas behavior therapists attempt to change behavior directly by using mainly nonverbal means, cognitive therapists . . . rely chiefly on speech as the instrument of change. (p. 356)

This artificial distinction is further elaborated by Ledwidge's later reference to cognitive therapies as "verbal therapies." The error of such a dichotomy is discernible on at least two counts. On one hand, the behavior therapist is reliant on verbal communication during treatment—a point that is in direct variance with Ledwidge's "nonverbal" attribution. More to the point, however, is the fact that persons labeled cognitive behavior modifiers are explicit in their emphasis on behavioral performance as a primary means of challenging maladaptive beliefs. Cognitive theorists ranging from George Kelly to Albert Bandura have been almost uniformly consistent in their reliance on active motoric performance in therapy (cf. Bandura, 1977a, 1977b; Beck, 1976; Kelly, 1955; Mahoney, 1977b; Meichenbaum, 1977).

In several places, Ledwidge (1978) recognizes the problems of distinguishing cognitive behavior modification and behavior therapy and the "somewhat arbitrary decision of choosing where on a cognitive-behavioral dimension to place a cutoff between the two types of techniques" (p. 357). The dependence of many cognitive techniques on overt behavioral and nonverbal means of effecting therapeutic change would make this distinction almost impossible. The ambiguity of the distinction between cognitive and behavior therapy is not the fault of Ledwidge. The problem is in trying to make distinctions at the level of techniques. At this level, what different therapists actually do often overlaps considerably, a fact that traditionally has served as an impetus for eclecticism or integration of seemingly incompatible theoretical positions. We, too, would have difficulty in making decisions using a single continuum based on a cognitive-behavioral dimension that would divide techniques, although extremes might be identified with agreement. At the conceptual level, distinguishing different forms of therapy is a more straightforward task, since the theoretical allegiance of a particular technique is readily identified.

Perhaps for clinical psychology as a whole, the most important distinctions among therapies are not made at the technique or conceptual levels. A dimension slighted in Ledwidge's (1978) review that is the most significant in distinguishing therapies is the commitment to empirical research as the crucible for treatment evaluation. Cognitive behavior modification is firmly committed to the tenets and practices of contemporary behavioral research. These include careful specification of treatment ingredients, multiple operationism of outcome, recognition of overt behavior as a major measure of treatment efficacy, and so on. In this regard, distinctions between select techniques, whether they are called behavioral or cognitive, tend to diminish. In the final analysis, it will, or should, be the theoretically sound and empirically established techniques that are embraced by the field. What these are called, how these develop, and the purity of their philosophical heritage will be interesting but not of ultimate importance.

Empirical Status

In his discussion, Ledwidge (1978) concludes that the data supporting cognitive-behavioral approaches are "meager" in comparison with the "enormous body of research validating the effectiveness of behavior therapy procedures" (p. 370). One could, of course, question whether behavior therapy procedures have been so overwhelmingly validated (e.g., Kazdin & Wilcoxon, 1976; Kazdin & Wilson, 1978). Likewise, one could question the classification of such procedures as imagery and modeling as behaviorally (rather than cognitively) oriented in

tervention strategies. More pertinent, however, may be Ledwidge's assertion that "the more cognitive the technique, the less effective it is" (p. 370). This is in ironic contrast to his concluding remark that judgment on the relative effectiveness of cognitive-behavioral strategies must be deferred until adequate research is available. Both explicitly and implicitly, it is clear that Ledwidge has already developed the hunch that cognitive-behavioral techniques are "a step in the wrong direction." This verdict is questionable on at least two counts.

First, there are now over a dozen studies that suggest that cognitive parameters may enhance either the predictive validity or the therapeutic power of previous techniques (Bandura, 1977a; Mahoney & Arnkoff, 1978; Meichenbaum, 1977). The potential of cognitive perspectives is most apparent in the recent studies by Taylor and Marshall (1977) and Rush, Beck, Kovacs, and Hollon (1977). In the former it was shown that a cognitive-behavioral therapy was more effective than isolated cognitive, behavioral, or no-treatment groups in the management of mild to moderately depressed subjects. The Rush et al. study found that cognitive therapy was more effective than chemotherapy (tricyclic drugs) in the treatment of severe depression—a finding that is noteworthy in its constituting the first (and only) psychological treatment to surpass tricyclic drug efficacy in this realm. Likewise, it appears that cognitively dictated "mastery experiences" may enhance the effectiveness of behavior rehearsal and participant modeling techniques (Bandura, 1977a, 1977b).

A second reason for questioning Ledwidge's (1978) verdict is its prematurity. Cognitive-behavioral approaches are relatively recent developments, and adequate opportunity to evaluate their mettle has yet to offer itself. Just as Ledwidge has expressed concern about the "wholesale conversion to cognitive methods on insufficient evidence" (p. 354), one might question the wisdom of premature rejection of such methods on equally insufficient grounds. There are, of course, cognitive theorists who have been generous in their evaluation and optimism regarding the current status of cognitive-behavioral approaches (e.g., Ellis, 1977). One might find equally enthusiastic proponents of almost any system of psychotherapy. On the other side of the coin, however, it is worth acknowledging that many defenders of the developing cognitive-behavioral interface seem to be well aware of the challenges that continue to face this area of inquiry (e.g., Bandura, 1977b; Beck, 1976; Mahoney, 1974, 1977a, 1977b; Meichenbaum, 1977). At least some of these sentiments were expressed in the lead article of that new journal "devoted entirely to cognitive therapy" (Ledwidge, 1978, p. 359). After a conservative statement on the status of cognitive-behavioral strategies, the need for continuing self-scrutiny was emphasized:

> In sum, our long and arduous journey has just begun. Let us not waste time congratulating ourselves on our wisdom when our ignorance is still so salient. We have cause for optimism, but hardly for jubilation. There are throngs of suffering humans who fill our waiting rooms, and we have yet to demonstrate that our therapeutic promises will serve them better than have those of the past. Let us bear in mind that our ultimate commitment is to these persons, and not to the esoteric needs of our paradigm. We must be ready to change when so doing would serve them better, and we must be every ready to follow new paths toward clinical effectiveness. (Mahoney, 1977b, p. 15).

Conclusion

Among the many problems that arise in the therapy literature, two seem to be particularly objectionable and dangerous. The first and certainly foremost is overzealously advocating treatment techniques based on anecdotal information and weak case material. Therapy techniques continue to be hailed as effective in professional and lay circles as if empirical evidence attesting to their efficacy were already available. Scientific criteria for endorsing existing treatments have yet to be uniformly embraced in the psychotherapy literature, not to mention clinical practice.

The second problem is judging, in advance of empirical research, the kind of techniques that might be effective and ruling out certain avenues based on this judgment. Ledwidge's

(1978) article discusses the beginnings of research on the many different forms of cognitive behavior modification but at the same time warns about the potentially undesirable consequences of embracing these techniques. Those who object to cognitive behavior modification for reasons that they believe to be conceptual or metaphysical should rejoice in the fact that this area is strongly committed to empirical research. If in fact cognitive based techniques add so little to existing techniques, this will be demonstrated rather soon, since research in cognitive behavior modification is proliferating so actively. Alternatively, if this research proves to be heuristically and clinically productive, as current evidence suggests, critics will be required to examine their own criteria for decision making.

The current state of cognitive behavior modification calls for accelerated research rather than second thoughts over further exploration. Objections based on the possible conceptual and methodological impurities that cognitive theory or therapy might introduce reflect a failure to appreciate the historical lineage and contemporary characteristics of behavior therapy. Behavior therapy is hardly free from sin in the sense of having many loose theoretical ends, techniques based on concepts that stretch (and use) the imagination, and assertions of efficacy that are poorly based (Kazdin, 1978). To imply that cognitive theory or techniques somehow tarnish all of this is difficult to maintain.

Cognitive therapy has thrown itself into the evaluative arena of empirical research. This is a risk that many forms of traditional therapy have yet to take. Along with the risk of demise should be the potential benefits of successes and empirical insights. At the very least, critics as well as advocates might be well advised to suspend judgment until the data accrue.

Cognitive Behavior Modification or New Ways to Change Minds: Reply to Mahoney and Kazdin

Barry Ledwidge
Simon Fraser University, Burnaby, Canada, and
Riverview Hospital, Port Coquitlam, Canada

The "myths" that (a) cognitivism necessitates mentalism and that (b) therapists can be classified on the basis of technique are defended. Two studies cited by Mahoney and Kazdin as evidence of the potential of cognitive perspectives are found, on close examination, to raise more questions than they answer. Charges of prejudgment and premature evacuation of the field are disclaimed, but it is urged that the phrase *behavior modification* not be used to describe cognitive approaches, since failure to distinguish the two kinds of therapy invites a conceptual confusion of cognition with behavior that could have unfortunate theoretical and practical consequences.

If it is possible to be damned with faint praise, then Mahoney and Kazdin's (1979) critique surely canonizes my position (Ledwidge, 1978) with faint criticism. Lacking adequate data, they fail to face squarely the central issues raised and instead attempt to shift the focus from treatment effectiveness to theoretical issues, including the old and bitter mind–body polemic. After dismissing as "sporadic" my review of the literature (which included a critical review of *every* article on cognitive-behavior modification published in any of the four behavior therapy journals between 1963, when the first issue of *Behaviour Research and Therapy* appeared, and July 1976, when I began writing the article) and after characterizing my conclusions as "only tangentially related to extant evidence," Mahoney and Kazdin then devote merely two paragraphs of their article to the empirical status of cognitive behavior modification and fail to cite any of the studies allegedly missed in my "sporadic review." The balance of their article is devoted to questions that are more semantic than real and that, by definition, cannot be answered empirically. It is to these pseudoissues that I now reluctantly turn.

The author would like to thank John Damron and Brian Cooney for their advice on substantive issues and comments on earlier drafts of this article.

Requests for reprints should be sent to Barry Ledwidge, Department of Psychology, Riverview Hospital, 500 Lougheed Highway, Port Coquitlam, British Columbia, Canada V3C 1J0.

Myths

I am taken to task by the authors for propagating two "persistent myths" that surround the "interface" of cognitive therapy and behavior modification. In the first place, according to Mahoney and Kazdin, I, like Skinner (1978) mistakenly assume that cognitivism necessitates mentalism.

What is a cognition, however, if not a mental event? A cognition is a behavior (albeit private), a hypothetical construct inferred from behavior to account for behavior, or a mental event in the bad sense of the word, that is, a causal event that is not reducible without remainder to either environmental, behavioral, or physiological events. The radical behaviorists, including Skinner, allow that private events (e.g., minute muscle movements detectable by an electromyograph) are acceptable for study but only if the investigator is able to reliably determine when the phenomenon occurs (Biglan & Kass, 1978). Verbal reports about cognitions qualify as behaviors in this sense, but the cognitions themselves do not. If cognitive behavior modifiers

were attempting merely to change the client's verbal reports about cognitions, then the treatment could be characterized as behavioral, but it is clearly the thoughts, beliefs, and attitudes of the clients and not just their speech acts that is the focus of treatment. Although radical behaviorists eschew the use of constructs (and theory building in general), methodological behaviorists are not averse to using intervening variables (e.g., Hull's r_g) to account for relationships among observable, environmental, and organismic events. If in fact cognitive behavior modifiers used cognition simply as a construct to account for enduring patterns of clients' responses to consulting room procedures, then there would be no confusion as to the status of a cognition. Unlike Hull, however, who never attempted to manipulate r_gs, Mahoney, Meichenbaum, Ellis, and others convert the intervening variable to a subject matter. (Mahoney and Kazdin, 1979, agree that "cognitive change is the active ingredient in treatment" [p. 1046].) If a cognition, then, as the term is used by cognitive behavior modifiers, is neither a behavior nor an intervening variable, then mental event remains as the most apt descriptor. To the extent that cognitive approaches appeal to causal events that are not environmental, behavioral, or specifically physiological, they are mentalistic. Hence, although Mahoney and Kazdin appear to repudiate psychophysical dualism, they are in a sense, tacit or "closet" dualists.

As evidence against my contention that cognitivism necessitates mentalism, Mahoney and Kazdin (1979) point out that in a soon-to-be-published survey (Mahoney, in press) involving 42 of the most eminent living contributors to behavior therapy and cognitive behavior modification, there were no significant differences in belief in the existence of a "mind." It does not surprise me that therapists of different persuasions have been able to accommodate in their lexicon this battered term. The question is whether the behavior therapists and the cognitive behavior modifiers surveyed mean the same thing when they say that mind exists. English and English (1958) list five definitions of mind, one of which might be acceptable to some behaviorists, namely,

> the organized totality or system of all **mental** processes or **psychic** activities, usually of an individual organism. The emphasis is upon the relatedness of the phenomena. Mind in this sense does not commit the user to a metaphysical position about the nature of these processes. Hence, it may be used by those who define psychology in terms of **acts** or **behaviors**. (p. 323; boldface in original)

The second "myth" that I am found guilty of propagating is that therapists can be categorized on the basis of the techniques they use. Mahoney and Kazdin (1979) point out that

> according to Bandura—and many other persons labeled "cognitive behavior modifiers"—the processes that govern human adjustment (and maladjustment) are cognitive in nature. (i.e., They involve attentional processes, aspects of information storage and retrieval, etc.) However, in almost comic irony, it now appears that behavioral procedures may be among the most powerful methods for activating those cognitive processes. Thus, if any clear distinction can be drawn, the major difference between cognitive and less cognitive behavior modifiers does not lie in their therapeutic procedures so much as in their rationale and selection of a given procedure in an individual case. The more cognitively oriented therapist is inclined to employ a behavioral procedure appropriate to the "cognitive restructuring" presumed to be required. (p. 1045)

The logic here is questionable. First we are told that cognitive behavior modifiers believe that the processes governing behavior are cognitive in nature. Mahoney (1977) asserts that the first premise of the cognitive-learning perspective is that "the human organism responds primarily to cognitive representations of its environments rather than to those environments per se" (p. 7). Then we are told that "in almost comic irony" (comical to behavior modifiers, ironic to cognitive behavior modifiers) behavioral techniques turn out to be the most efficient methods of changing these hypothetical constructs (an implicit endorsement of behavior therapy). Faced with data which indicate that human organisms respond primarily to the environment rather than to cognitive representations of it, Mahoney and Kazdin (1979) resolve this embarrassing theoretical paradox by asserting that although cognitive therapists and behavior therapists often use the same techniques, the best way

to distinguish them is on the basis of the rationale each uses for selecting a technique.

Surely, technique is the only logical basis for classifying therapists. Of what difference is it to the client whether the therapist's intent, when administering a procedure, was to reinforce discriminative operants, change irrational thought patterns, or strengthen the ego? Are we to believe that when participant modeling, administered by a cognitive therapist, results in a decrement in avoidance responding, it does so for different reasons (cognitive changes) than when it is used successfully by a therapist who does not consider cognitive change the active ingredient in participant modeling? Surely all therapists, including cognitive behavior modifiers, should base their choice of technique on empirical evidence of its effects on behavior and not on any theory associated with the technique.

Empirical Status

Two studies published after I had completed my review of the literature are cited as evidence of the potential of cognitive perspectives. One of these, Rush, Beck, Kovacs, and Hollon (1977), found that cognitive therapy was more effective than imipramine in the treatment of depressed outpatients. The treatment procedure used by the cognitive therapists is not specified, but we are referred to 43 pages of a book by one of the authors (Beck, 1976, pp. 263–305) and are told that

> the cognitive therapist employs both verbal and behavioral techniques to help the patient learn to (a) recognize the connections between cognition, affect, and behavior, (b) monitor his negative thoughts, (c) examine the evidence for and against his distorted cognitions, and (d) substitute more reality-oriented interpretations for his distorted negative cognitions. (pp. 18–19)

One wonders exactly what went on in these cognitive therapy sessions. Cognitive behavior modification may be firmly committed to the tenets and practices of contemporary behavioral research, but cognitive therapy does not lend itself to empirical investigation as well as does behavior therapy because some parameters of cognitive therapy cannot be specified. How does one operationally define, for example, a cognitive technique "to help the patient recognize the connections between cognition, affect, and behavior?" One wonders, too, how much of the cognitive therapy in the Rush et al. study consisted of verbal techniques and how much consisted of behavioral techniques. Would a straight behavior modification approach (e.g., differential reinforcement of depressive and nondepressive behavior by the patient's spouse or another significant person) have been more effective? These questions seem particularly relevant in the light of the findings of the second study cited by Mahoney and Kazdin (1979). Taylor and Marshall (1977) found that cognitive therapy and "behavioral intervention" (speech—verbal nonassertiveness—was the only behavior treated) were equally effective in reducing depression but that a combination of the two verbal approaches was more effective than either technique used singly. A behavior therapist might reasonably ask whether behavioral treatment of a broader spectrum of depressive behaviors (including speech) would prove superior to cognitive therapy or the combination treatment of Taylor and Marshall.

Conclusion

In their discussion, Mahoney and Kazdin (1979) accuse me of "judging, in advance of empirical research, the kind of techniques that might be effective and ruling out certain avenues based on this judgment" (p. 1047). The charge of prejudgment is supported by an out-of-context quote from my article (Ledwidge, 1978), in which I am alleged to have concluded that "the more cognitive the technique, the less effective it is" (p. 370). In context, the statement above turns out to apply only to one of three types of data reviewed (comparisons of two variants of the same behavior therapy technique in which one of the procedures relies less on cognitive operations than does the other and/or has extra behavioral components as part of the procedure). Seven such comparative studies were presented (including two by Bandura and his colleagues [Bandura, Blanchard, & Ritter, 1969; Bandura & Menlove, 1968]),

six of which showed that the more cognitive the technique, the less effective it was. Bandura (1977) has come to the same conclusion: "Regardless of the methods involved, results of comparative studies attest to the superiority of performance-based treatments" (p. 196).

At no point in my article did I recommend, as Mahoney and Kazdin (1979) imply, that research on the effectiveness of cognitive therapies be discontinued; in fact, more research and deferred judgment were called for:

> Existing CBM procedures may in time be shown to be as effective as behavior therapy with clinical disorders, or new and more effective cognitive methods may yet be devised. As documented earlier, cognitive behavior modification is of recent origin, and only a handful of studies have appeared in the journals so far. Until comparisons of behavior therapy and CBM are carried out with clinical populations, however, judgment on their relative effectiveness must be deferred (Ledwidge, 1978, p. 371)

The emphasis I intended to impart was that this new hybrid therapy should not be called cognitive behavior modification because it is not behavior modification. Cognitive therapists are engaged in a radical departure from the methodology of behaviorism in treating cognition as subject matter rather than as an intervening variable. I hoped to point out how failure to distinguish the two kinds of therapy invites a conceptual confusion of cognition with behavior that could have unfortunate theoretical as well as practical consequences.

If the requested name change sounds like school chauvinism, it is because it is. The hard-earned excellent reputation that behavior modification enjoys today would be tarnished if cognitive behavior modification proves no more effective than more traditional forms of psychotherapy.

Psychobiology of Active and Inactive Memory

Donald J. Lewis
University of Southern California

A brief history and review of the short-term memory and long-term memory distinction is presented, and this distinction is concluded to be no longer adequate for either human or animal memory data. Simple memories for events are apparently formed quickly and are permanent. In such cases, an initial physiologically unstable period is not required. Thus, most forgetting is the result of a retrieval failure rather than a storage failure. A distinction between active memory (AM) and inactive memory (IM) is made. AM is a subset of IM and contains either newly formed memories or established retrieved memories or both. Some of the implications for psychobiology of the AM and IM distinction are discussed. It is suggested, for example, that while in AM, memories are particularly open to disruption either by amnesic agents or through other forms of interference. The forgetting process for new and established memories is time dependent (but independent of memory age) and is based on interference. It is desirable to maintain the distinction between memory storage and memory retrieval even while recognizing that associative storage aids in retrieval. The search for the biological basis of rapidly forming memories, perhaps based on the restructuring of protein fragments, remains important but the physiological brain processes underlying memory interference and retrieval require greater emphasis.

The distinction between short-term memory (STM) and long-term memory (LTM) has been a useful and productive one in both animal physiological psychology and human cognitive psychology in recent years. There is not total agreement on the characteristics of STM, but most agree that (a) STM is either the route of entry to LTM for new memories or at least the holding template until LTM processes are complete; (b) the contents of STM are temporary and fragile, either decaying rapidly, open to disruption, or transferring rapidly to LTM; and (c) the capacity of STM is limited to a few items at one time. LTM, on the other hand, stores memories relatively permanently and has almost unlimited capacity. There are many variations on these characteristics, some of which are discussed later. The purpose of this article is to show that the distinction between a temporary and fragile memory and one that can become permanent is no longer adequate for the preponderance of the data in either the animal or the human fields. A more adequate alternative is to consider all memories as long-term or permanent, with a few of them being active at any given time and the remainder of them in an inactive state. A brief history of the STM–LTM distinction will demonstrate why this is a more adequate alternative.

Precursors

William James (1890) introduced the term "primary memory," by which he meant the perceptions, images, sensory impressions, perceptual processes, concepts, and mental entities of any sort that occur as the result of external stimulations during learning. The items of primary memory are part of the psychological present. James used the term "specious present" to indicate that the con-

Requests for reprints should be sent to Donald J. Lewis, Department of Psychology, University of Southern California, University Park, Los Angeles, California 90007.

cept of the present was more apparent than real because what seemed like the present was overlaid by a great deal of the past and the future. This was part of James's firm insistence that consciousness was continuous and that any attempt to break it into parts was artificial. The "real" memory was his secondary memory, into which items could be stored and retrieved. For James, retrieved memories, even at the time of retrieval, were in secondary memory.

After James (1890), classical interest in primary memory focused on the number of items that could be simultaneously present. This line of research culminated in G. A. Miller's (1956) "magical number seven," consolidating the agreement among many studies that on the average, only seven items could be held in immediate memory and proposing the concept of "chunking," by which the amount of information could be greatly increased while retaining the limitation of approximately seven items.

Working in the field of verbal learning, Müller and Pilzecker (1900) attempted to explain the data on retroactive interference—that the learning of a second list of verbal materials causes the forgetting of a previously learned list. They argued for two physiological processes: first, a perseverating neural process that was maintained until, second, a more permanent memory structure was formed. During the perseverative phase, the neural process was open to disruption, and thus the second list of verbal materials disrupted the neural perseveration initiated by the first list before it could become a permanent physical structure. Müller and Pilzecker's "consolidation theory" has had an immense impact on neurological investigations of learning, even though its influence on verbal learning, for which it was originally proposed, has been minimal. A major reason for the neglect of perseveration theory by cognitive researchers has been the recognition of proactive interference; forgetting can be caused by the learning of verbal materials occurring long *before* the learning of materials whose forgetting ensues. Although retroactive interference could be due to a totally different forgetting mechanism than proactive interference, an unnecessary lack of parsimony would be required. Further, the finding that a major determinant of both retroactive and proactive interference was the similarity of the learned items turned researchers away from neurological concepts, since verbal similarity seemed difficult to conceptualize neurologically.

Ebbinghaus (1913) also proposed the possibility of two different memories, although his distinction was based on the number of items to be learned. If 6 or 7 nonsense syllables were to be committed to memory, only one trial was typically required, whereas 12 syllables required almost 15 repetitions. This discontinuity implied two different processes to Ebbinghaus, although it was not a distinction between an STM and an LTM, since both processes committed items to LTM.

Following Ebbinghaus (1913), researchers showed little interest in a STM–LTM distinction until the late 1940s, at which time both physiological psychologists and human cognitive psychologists became interested but with different orientations. The cognitivist interest grew out of research on information processing (Broadbent, 1958) and paid little attention to physiological work. Hebb (1949) renewed the interest of physiological researchers, who were in turn little concerned with the informational approach. In both fields there was an initial marked enthusiasm for two-process theories, an enthusiasm that later became tempered by skepticism and, in many cases, outright rejection.

Human Cognitive Conceptions

Experimental

Broadbent (1958) attached earphones to his human subjects and simultaneously presented two sets of three or four digits, one set to each ear, and the subjects were asked to recall each set. Broadbent found that subjects usually attended to only one set of digits and could recall this set perfectly. But they could also recall some of the second set even though the rate of presentation was too fast to permit the switching of attention from one ear to the other. From this, Broadbent concluded that there must be a temporary storage system, an STM, in which the second

set of digits was held momentarily, until attention could be turned to it. He conjectured that this storage system could hold the information only for a few seconds and that items that were not attended to within this time decayed and disappeared. Although Broadbent's STM mechanism was more complicated than has just been described, its essential features were (a) rapid decay rates, (b) continuing processing necessary to maintain items in STM, and (c) a limited capacity of only two to four items. Broadbent believed that these features of STM necessitated its distinction from LTM, which possessed none of these properties. Forgetting in LTM, he believed, was due to the interference produced by other memories and not to decay; items could be held in LTM indefinitely and without effort unless there was specific interference; the capacity of LTM was virtually unlimited.

Peterson and Peterson (1959) and Brown (1958) independently introduced both a new experimental procedure to study STM and additional data and theory to support the separation of STM from LTM. They presented a verbal unit consisting typically of three consonants—a trigram. If recall occurred immediately after a presentation, performance was usually perfect. If immediately after presentation of the trigram subjects were required to count backward by threes from a given number, there appeared a sharply decelerated "decay" function with retention almost at zero after an 18-sec delay. Here was good evidence for rapid forgetting, if the items could not be held continuously in STM, and Peterson and Peterson and Landauer (1974) supported a time-dependent decay theory of forgetting from STM, a notion very similar to that of the Müller and Pilzecker (1900) theory. This theory, you recall, had fallen into disuse in part because of the evidence that forgetting was produced by interference that was caused by the similarity between the target information and the interfering information. Further, this similarity could be defined on the bases of the semantic properties of the material. "House" and "dwelling," for example, would interfere greatly with each other, even though they had dissimilar physical features.

Thus, evidence presented by Conrad (1963) and Sperling (1963) that interference also occurred in STM was important. This interference, however, was acoustic in nature rather than semantic; for example, subjects would respond with an F when S was the correct trigram letter. Therefore, STM was still considered distinct from LTM, but acoustic interference replaced rapid decay in part, at least, as a distinguishing feature of STM. Important cognitive theories advanced at about this time incorporated conceptually different memory components, either as a physical store, a process, or both (e.g., Atkinson & Shiffrin, 1968; Glanzer, 1972; Waugh & Norman, 1965). Probably, by the end of the 1960s, a majority of the cognitive learning researchers accepted STM as real and distinct from LTM, even though the notion of a decaying or a consolidating engram (Müller & Pilzecker, 1900) never attracted a substantial number of adherents. (Nevertheless, see Hintzman, 1974, who considers consolidation a possible explanation for the "spacing effect," an improvement in retention when the interval between repetitions of certain verbal materials varies from 0 up to 15 sec.)

Amnesic Syndrome

Humans who have suffered damage to the hippocampus and/or areas around the walls of the third ventricle frequently show a profound learning and memory impairment of an extraordinary nature. Upon hearing a series of digits, they can repeat correctly as many as can normals, and they can carry on a normal conversation, which means they can hold in memory the early part of a message and use it to unitize the thought. They also appear to remember events that occurred before their injury. If they have a normal memory for current events and also for events prior to injury, why are they characterized as amnesics? They appear to be unable to transfer current memories to the long-term store. A conversation they have today, for example, will be forgotten tomorrow. STM and LTM each seem clear and distinct, but

new information does not appear to enter LTM. The most famous of these amnesics is H.M. (Milner, 1966, 1970). H.M. was a severe epileptic who underwent a bilateral hippocampectomi, after which he seemed unable to add any new information for later retrieval. No matter how many days in a row he had a conversation with a person, he could not remember the person's name or anything about the previous conversation on the next day. Other than this deficit, his behavior was not notably abnormal. There are many others who suffer from the amnesic syndrome as a result of brain damage, and, although their symptoms may vary slightly, they have in common an inability or difficulty in remembering events beyond a short period of time (Talland, 1968). This sort of dichotomized memory function seemed to demand a distinction between an STM and an LTM, and Atkinson and Schiffrin (1968), in their theoretical treatment of memory, characterized the amnesic syndrome as the single most convincing piece of evidence for a distinction between STM and LTM.

Arguments Against a Human STM–LTM Distinction

Experimental Evidence

Although the arguments and data supporting an STM–LTM distinction at the human level are strong, there has been considerable dissent from this position, a great deal of it centering around the Peterson-Brown (Brown, 1958; Peterson & Peterson, 1959) experimental procedure.

Melton (1963) had argued that one of the major distinguishing features of LTM was its openness to interference and that to the extent that a putative STM and the LTM showed identical interference effects, there would be no necessity to posit separate memories. Keppel and Underwood's (1962) demonstration that a considerable amount of the forgetting occurring in the Peterson-Brown procedure was due to proactive interference was thus a powerful support for a single-memory conceptualization. Then, Waugh and Norman (1965) (see also Glanzer, 1972; Wickelgren & Norman, 1966) showed that the number of interfering items was more important in producing forgetting in the short-term paradigm than the simple passage of time. The similarity among items has also been demonstrated as a cause of STM forgetting. Deutsch (1970), for example, produced greater forgetting of tone sequences when the interpolated material was also tonal than when words were used. Wickelgren, in a series of studies (e.g., 1965), showed both proactive and retroactive interference in STM when the learning and interfering materials were acoustically similar.

The evidence thus shows that both proactive and retroactive interference occur in STM and that this interference is the major cause of STM forgetting. Any simple decay (Reitman, 1974) that remains does not seem to be of much importance. Basically, these data seemed to support Melton's (1963) contention that if the putative STM obeys the same laws as LTM, there is no reason to assign it a separate existence. But interference may be acoustic in STM and semantic in LTM.

Assuming a separate STM, how is the transfer of memories made to LTM? Items are both maintained in STM and transferred to LTM through rehearsal. But rehearsal need not refer only to the holding through repetition of items in STM for a period of time. Craik and Watkins (1973) showed that simply maintaining items in STM for 10–20 sec did not improve their strength in LTM. (See Craik, 1979, for more detailed discussion.) Some form of coding is necessary to retain an item permanently. Ample evidence now exists that semantic coding does take place in STM (e.g., Shulman, 1970, 1972). There may still be a difference in the degree to which semantic coding takes place in STM and LTM, but the difference is not dichotomous and therefore neither are the memories on this basis. These coding studies have yielded a useful distinction between maintenance rehearsal and coding rehearsal. The simple holding or maintaining of an item in STM for a period of time, as has been indicated, aids little in its retrieval from LTM unless some coding operation is performed on it. It is the type of activity that occurs during

rehearsal that is crucial in STM itself, not the passage of time.

That different types of coding do occur in STM has helped to blur an STM–LTM distinction based on what has been called the "negative recency effect" (Madigan & McCabe, 1971). For immediate recall both the first and last items of several in a list are better retained than those in the middle. The usual explanation is that more attention and rehearsal can be devoted to the first items simply because they are first, whereas the last item is well retained because it is still in STM. Delayed recall, however, yields a negative recency because the last item received little rehearsal compared to the early items, and it is no longer in STM. But when appropriate coding is used (Bellezza & Walker, 1974), the usual positive recency is found also for delayed recall. Tulving (1968, 1974) has taken the view that there are two retrieval processes involved in recall rather than two storage processes. Early after item presentation, temporal and phonemic retrieval cues are effective. Later on, semantic cues are better. Murdock (1974) gives an intuitive example of this distinction. You are directing someone to pick up your suitcase from an airport conveyor discharge belt. "It is the one that has just come down the chute" would be one type of instruction. If it has been on the belt for some time, a different type of code would have to be used such as, "It is the blue one with the torn grip."

Based on the experimental data produced by cognitive learning psychologists, it seems fair to conclude that there is as yet no convincing reason to require a separate STM. But what of the evidence derived from the amnesic syndrome?

Amnesic Syndrome

H.M. had a normal immediate memory span, you recall, but he could not recognize people he had met many times or even recall yesterday's conversation. It was believed that he was unable to transfer memories from STM to LTM, supporting the notion of the independent existence of the two. Further studies, however, showed that H.M. could retain certain visual and tactile maze tasks (Corkin, 1968). H.M. also had some knowledge that he had a memory impairment (Milner, 1970), and he had learned a factory job, although he could not describe it. He knew that President Kennedy was assassinated, but he did not know who succeeded him. Perhaps one might conclude that H.M. has an aphasic deficiency in coding new information so that it can be recognized later. If so, the deficit is one of retrieval rather than of storage. Other evidence from amnesics lends support to this hypothesis in that with appropriate retrieval probes, memories can be recovered (Weiskrantz & Warrington, 1975). This point is discussed in greater detail later.

The phenomenon of retrograde amnesia (RA) is the memory loss caused by a brain trauma, a loss that is most severe for events just prior to trauma and is progressively less further into the past. This gradient is one of the bulwarks of consolidation theory (Glickman, 1961; Mah & Albert, 1973; McGaugh, 1966; Müller & Pilzecker, 1900), which requires new memories to be more open to disruption than older ones. As memories age, they harden and become relatively permanent. There are numerous observations, however, that are not consistent with the notion of a consolidating memory trace. (a) Many patients are amnesic for events that extend back a matter of years. (b) Shrinkage of amnesia is a frequent occurrence. The shrinkage indicates that during amnesia the memory existed but simply was not accessible. Shrinkage strongly suggests a failure to retrieve, not a failure to consolidate or to progress from STM to LTM. (c) RA frequently is spotted with islands of remembering that have no temporal continuity, and RA can involve condensing two events into one (Talland, 1968). The amnesia shrinks, but it is not a consistently temporal process moving forward in time. More islands appear, and only later does temporal coherence return. (d) Amnesics have difficulty remembering specific events but can remember well-categorized information or generalized information. They can, for example, remember that flags are for waving in a parade, but they do not remember a specific flag or a specific parade (Wood &

Kinsbourne, Note 1). (e) Amnesics frequently can learn motor skills and perceptual tasks even though they forget when or how they learned them (Milner, 1970; Warrington & Weiskrantz, 1970). (f) Proactive and retroactive interference can explain much of the forgetting of amnesics (Weiskrantz & Warrington, 1975).

In an excellent review of the amnesic syndrome, Kinsbourne and Wood (1975) argue that the reason that there appears to be a temporal gradient in many amnesics is that patients are asked different types of questions about the recent past than about the remote past. The questions about the remote past tend to be more general and categorical (semantic), except for the case history type of information that has undoubtedly been frequently rehearsed. Specific temporally related questions (episodic), on the other hand, are asked about recent events, and, since amnesics have trouble remembering specific events about any period of their life, there is the appearance of the forgetting of recent events. Kinsbourne and Wood related the forgetting that is characteristic of the amnesic syndrome to the distinction made by Tulving (1972) between episodic and semantic memory. Episodic memory is for specific events, episodes, or contexts. Semantic memory is about rules, categories, generalities, relations, and associations and can be context free. The forgetting of amnesics is characteristically episodic, whereas their semantic memory remains normal. The apparent time gradient in amnesics is due more to the nature of the interview, which focuses on episodic material for recent events and semantic material for remote events.

Kinsbourne and Wood (1975) reviewed the experimental work on amnesics that has been done using the Peterson-Brown paradigm. The basic results of their review suggest strongly that amnesics performed more poorly on the STM task than did normals, but the forgetting curve was parallel for amnesics, and for normals over an interval from 3 to 18 sec, there was no interaction between the groups. This indicates that the STM memory process is the same for both groups; they forget in the same fashion but differ simply in the amount that is forgotten. Also, the amount of interference interacts with retention time in the same way for both. Kinsbourne and Wood cite studies (H. Gardner, Boller, Moreines, & Butters, 1973; Wood & Kinsbourne, Note 1) in which subjects were told at retrieval time which category the words that they were required to learn were taken from, and retrieval was aided. Similar information at the time of learning had no effect. They concluded that "the balance of the evidence favors a retrieval explanation of the amnesic defect in short-term memory as measured in the Peterson and Peterson paradigm" (Kinsbourne & Wood, 1975, p. 277).

Conclusion

It seems clear that for those who wish still to hold to the distinction, STM and LTM share two important features: (a) Interference is a major determiner of forgetting in both, and (b) they both involve articulatory and semantic coding, although STM probably makes a greater use of the former. There remain differences: (a) Maintenance rehearsal can occur in STM but not in LTM, and (b) STM is ordinarily viewed as a port of entry into LTM for new memories or a temporary holding template until a permanent memory is formed. On the basis of the human data and observations, however, there is little support for the notion that STM is necessary for the firming of a physiological memory trace in the sense that Müller and Pilzecker (1900) originally posited or that the passage of time alone in STM allows the trace to consolidate, a conception that still prevails among animal physiological psychologists (Gold & McGaugh, 1975). Memories seem to be transferred to LTM by "mental" operations, such as the various forms of coding that can occur with the speed of the neural impulse, and the source of the forgetting seems to be at retrieval rather than storage.

This conclusion is shared by Isaacson and Pribram (1975), who, in writing a summary for their book on the hippocampus, say,

> any simple, long-term memory consolidation hypothesis of hippocampal function based on the initial findings with human subjects has become untenable in

the light of subsequent analysis. Unfortunately, this hypothesis is still held by the majority of people not actively involved in hippocampal research. (p. 43)

This is a conclusion similar to that of Weiskrantz and Warrington (1975) who say, "the amnesic deficit appears to be with mechanisms beyond the initial input into storage" (p. 413).

The quantity of surgical, chemical, and electrical intervention that has gone into animal research on this topic has not been possible with humans. It is time now to turn to animal research. There is, of course, no guarantee that human and animal memory processes are the same or even similar, but since Pavlov's studies on the dog, marked commonalities in learning have appeared, and it is not unreasonable to assume that the same will be true for memory.

Evidence From Animal Studies

General

Research on animal memory has been undertaken largely by physiological psychologists whose basic purpose has been to discover those physiological processes that accompany and probably are an essential part of learning. Since learning is a relatively permanent change in behavior, a basic assumption is that a physical structure must be involved. It is assumed that a time period is necessary for the structure to form, but it is also clear that there is memory almost instantaneously following stimulation. Therefore, some process intervening between stimulation and final structure has been assumed to be necessary. Hebb (1949) assumed that reverberatory electrical process could maintain the memory until the structure was formed. But most would agree that the electroconvulsive shock (ECS) studies convincingly demonstrate that this cannot be true. First of all, ECS sets up an electrical storm in the brain that totally overwhelms the kind of patterned electrical activity posited by Hebb. In addition, there is an almost total isoelectric period following ECS that does not permit patterned electrochemical neural transmission.

Hebb's is a two-process sequential model, with STM leading to and triggering the LTM. Two-process parallel theories have also been proposed in which both STM and LTM are initiated simultaneously at the time of learning, but the STM drops out after a critical period, leaving LTM to carry the memory. Gold and McGaugh (1975) have proposed a single-trace but two-process memory system. The trace is formed immediately at acquisition, but it fades and disappears unless some hormonal process follows that produces a memory fixation. Each of these alternatives is considered to be a form of consolidation theory in that each requires an initially fragile period for memory during which it is open to disruption or fading.

Evidence for STM–LTM

Duncan (1949) performed the classical study that showed that test performance was a function of the interval between a learning trial and the administration of ECS; the closer in time the ECS is to the learning event, the less the test performance. This function was called "the gradient of retrograde amnesia" and is one of the most well-established facts in the memory literature. In an influential article, Glickman (1961) reviewed the ECS literature and concluded that this gradient reflected the period for the consolidation of the learning trace. Although there was sporadic disagreement about this conclusion (see Coons & Miller, 1961; Lewis & Maher, 1965, 1966), it was vigorously reaffirmed by McGaugh (1966).

Methodologically, research moved from the use of multiple learning trials and multiple ECSs (Duncan, 1949) to single trials and single ECSs. Single learning trials were used because the age of the learning trace was made more determinate, and single ECSs were used because data showed that whereas several ECSs had marked punishing effects, one usually did not (Hudspeth, McGaugh, & Thomson, 1964). Experiment after experiment has been reported over the past decade in which a "time-dependent" amnesia has been found. The gradient varies with the intensity of the reinforcer used in acquisition (Mah & Albert, 1973), with the intensity and duration of the amnesic agent (Alpern & Mc-

Gaugh, 1968; Buckholtz & Bowman, 1972), and with other experimental conditions (Cherkin, 1969). Amnesia gradients have been produced with convulsant drugs (Pearlman, Sharpless, & Jarvik, 1961), hypothermia anesthetics (Alpern & Kimble, 1967), as well as electrical stimulation of the brain. The most widely accepted conclusion has been that the effect is on the storage of information and that at least indirectly, the gradient reflects the time for memories to pass from a fragile phase to a more permanent one (McGaugh & Dawson, 1971). Originally it was believed that ECS totally disrupted the consolidation process and destroyed the memory (Luttges & McGaugh, 1967), but now consolidation is believed to slow down and speed up depending on a number of experimental conditions (Mah & Albert, 1973), and the disruption may leave a partial memory that can later be reactivated and become fully consolidated and permanent (Cherkin, 1972; Kesner, 1973).

Additional support for the consolidation theory came from studies in which a block in protein synthesis in the brain coincided with a memory block (J. B. Flexner, Flexner, & Stellar, 1963; L. B. Flexner, Flexner, & Roberts, 1967). Various antibiotics injected into the brain or administered subcutaneously were shown to disrupt the formation of new protein by as much as 95%, and a memory impairment for recently acquired information was produced as well. Since, it was conjectured, a new structure mediating LTM must involve protein formation, a plausible mechanism for permanent memory seemed at hand. Further, injections of the protein synthesis inhibitor cycloheximide (CYCLO) before learning did not prevent normal initial acquisition nor did it interfere wth memory until several hours (3 to 6) had passed (Barondes & Cohen, 1968a, 1968b), by which time severe memory decrements had been observed. Thus, CYCLO seemed to be acting specifically on LTM while leaving STM intact. A similar conclusion may be drawn from data showing that memory is intact shortly after ECS (Geller & Jarvik, 1968) but disappears rapidly thereafter. Originally it was believed that ECS disrupted the consolidation of STM, but these later data are interpreted to mean that STM is left intact, and the interference is with LTM or with the transfer from STM to LTM.

The locations of physical sites in the brain for these effects have been pinpointed. Amnesia can be reduced if subseizure electrical current is administered to the hippocampus (Kesner & Connor, 1972, 1974), the caudate nucleus (Wilburn & Kesner, 1972), the substantia nigra (Routtenberg & Holtzman, 1973), the thalamus (Mahut, 1962), the midbrain reticular formation (Glickman, 1958), and the amygdala (McDonough & Kesner, 1971). (See McGaugh & Gold, 1976, for a review of these studies.) In each case the amnesia was time dependent. Bloch (1976) provides evidence for the notion that consolidation can be speeded up as well as slowed down. Time-dependent phenomena are again prevalent and time dependency is widely deemed to uniquely reflect the progressive formation of a new permanent memory structure and the fading or decay of an STM.

Evidence Against STM–LTM

Some data causing difficulties for the traditional consolidation of a STM into LTM are reviewed, and some of the newer theoretical notions are introduced. The negative data concerning the dichotomy between STM and LTM are treated more extensively than the positive, since that dichotomy is less widely accepted.

General

The supreme difficulty with the early consolidation theory (McGaugh, 1966) was that it failed to take sufficient notice of the learning–performance distinction (see Lewis, 1969). Thus, the behavioral deficits produced by amnesic agents administered at the time of learning were believed to be a direct reflection of the consolidation engram. Insufficient attention was paid to the many reasons why animals fail to perform other than that they no longer have any memory for what was learned. As a consequence, the RA gradient was believed to reflect the length of time during which STM remained open to disruption. This was generally believed to be a matter of

seconds or a few minutes at most (Glickman, 1961), and since the engram was a chemical–electrical–physical event encased in a relative constant physiological environment, its consolidation time was assumed to be relatively invariant. This latter assumption turned out to be far from the truth. Consolidation gradients had great variability from approximately 10 seconds (Chorover & Schiller, 1965) to 6 hours and more (Kopp, Bohdanecky, & Jarvik, 1966). It became necessary to consider the empirical RA gradient as reflecting only the period of susceptibility to disruption of the memory and not as the actual consolidation time. The reports that the consolidation time could be reduced to less than .5 sec (Lewis, Miller, & Misanin, 1968, 1969) if the animals were well familiarized with the learning environment before the introduction of footshock (FS) and ECS were often overlooked. (See Dawson & McGaugh, 1969b, for a failure to replicate; and Hinderliter, Smith, & Misanin, 1973; Jensen & Riccio, 1970; Miller, 1970; Riccio & Stikes, 1969, among others, for positive instances.) Lewis et al. (1969) suggested that learning occurred with the speed of the neural impulse and that ECS as ordinarily administered must be affecting a retrieval process, not a storage one. If amnesia is due to a retrieval failure, then RA gradients are not informative about consolidation time or memory fixation.

Attributing the action of an amnesic agent that is administered at the time of acquisition to a retrieval process has seemed illogical to some researchers. They prefer to believe that experimental agents acting at acquisition must be on acquisition processes and that only agents acting at the time of retrieval can be on retrieval processes. Many human cognitive psychologists, however, have long believed that interpolated learning has its effect on retrieval mechanism, even though the interpolated learning closely follows the original learning, and the test is much later. Interpolated learning may not work in the same fashion as an amnesic agent, but the point is that the proximity of the forgetting agent to original learning need not demand that any memory deficit be due to storage failure.

Reminder and Recovery

Another difficult problem for the storage failure point of view rose when the "reminder" studies began to appear (Koppenaal, Jagoda, & Cruce, 1967; Lewis et al. 1968). The basic assumption of these studies was that ECS served to inhibit or block the retrieval of memory rather than disrupt its formation. This approach assumed that memories endured through ECS, but access to them was temporarily lost. If so, then a reminder—a portion of the original learning situation—should return them to expression. Miller and Springer (1972) explored the reminder effect in detail and found it to be independent of the ECS-reminder interval or the reminder-test interval. Also, it occurs in appetitive situations as well as those of avoidance.

A significant extension of the reminder effect was reported by Quartermain, McEwen, and Azmitia (1970). They used CYCLO to bring about a deep inhibition of protein synthesis and an amnesia. Nevertheless, a reminder stimulus produced a memory return, which suggested strongly that whatever the effect the inhibitors of protein synthesis had on memory, it did not block its formation. It must be understood that the effect of any drug on memory depends on many conditions other than the drug itself, such as the strength of the memory and the test conditions. Nevertheless, the role protein synthesis inhibition plays in memory formation is probably not great, if it plays a role at all. At least memories can be fully recovered even when protein synthesis is inhibited over 90% (Quartermain, 1976).

Lost memories can also be returned to expression pharmacologically. Perhaps the first clear demonstration of this was the Braun, Meyer, and Meyer (1966) study in which a visual discrimination was lost following extirpation of the posterior cortex of the brain but was relearned rapidly, compared to controls, on injections of DL-amphetamine. Adams, Hoblit, and Sutker (1969) have returned memory to expression following ECS with injections of physostigmine. Roberts, Flexner, and Flexner (1970), Serota, Roberts, and Flexner (1972), and

Botwinick and Quartermain (1974) also have induced memory recovery pharmacologically following a memory lapse due to protein synthesis inhibition. Perhaps the most important recoveries have been reported by Rigter and Van Riezen (1975). (See Barraco & Stettner, 1976, and Meyer & Beattie, 1977, for more detailed reviews.) The recovery of memory following protein synthesis inhibition shows that there could not have been a permanent loss of LTM even though memory seems to disappear approximately 6 hours after acquisition.

Interestingly, protein synthesis inhibition compounds also reduce the amount of available norepinephrine (NE) and other biogenic amines, and Serota et al. (1972) proposed that a NE deficiency lies behind the amnesias. If so, Quartermain (1976) has shown that the effect is on memory retrieval and not on its formation in that he has found a spontaneous recovery of a T-maze memory for which amnesia had been produced by the inhibition of NE synthesis. Barraco and Stettner (1976) conclude, "we believe that the leading hypothesis at present should be that antibiotics block or impair retrieval processes providing access to memories for specific aspects of training" (p. 271). They add that puromycin may be an exception to this conclusion.

The fact that memory either recovers spontaneously, recovers on reminder stimulation, or is recovered pharmacologically indicates that the amnesias are not due to the failure of memory formation, either short term or long term. Reminder stimulation has not been tried in all situations, and therefore this conclusion must remain tentative, but the body of evidence on amnesia strongly suggests that a retrieval mechanism is involved and that a multiple-stage memory formation theory is not necessary for currently existing facts.

Cue-Dependent Amnesia

Another block of evidence that runs counter to a two-process memory conception comes from studies on cue-dependent amnesia. These studies suggest a different variety of memory processing of a cognitive type (Lewis, 1976), which is discussed later. The first cue-dependent amnesia experiment was that of Misanin, Miller, and Lewis (1968; but see Schneider & Sherman, 1968, for a similar experiment with a different point of view). First, the animals learned an avoidance response cued to a tone. Twenty-four hours following learning, after any consolidation process should have been completed, the animals were returned to the learning apparatus, the tone was presented, and it was immediately followed by ECS. Twenty-four hours after treatment, the animals were returned for testing, and those that had received ECS in the presence of the learning cue were amnesic. The implications of this study were considerable. It suggested that the age of the memory was not an essential determiner of whether or not amnesia would be produced by ECS and that amnesia was not dependent on a memory's early fragility. An immediate implication was that the RA gradient was not conclusive evidence of consolidation failure or even of a susceptibility to storage disruption (Lewis, 1969). The Misanin et al. (1968) study also showed that ECS had to be given in the presence of a learning cue from the learning situation for memory to be disrupted, and for this reason the effect has been called cue-dependent amnesia.

Misanin et al. (1968) speculated that the presence of the cue served to reinstate the memory and that the simultaneous presence of ECS with the memory served to inhibit or block the later expression of that memory. In other words, the memory must be evoked for it to be blocked by ECS and presumably by other amnesic agents. This reasoning led them to make a distinction between active and inactive memories. Learning always occurs in the presence of specific cues and a contextual environment, and to the extent that these cues and context occur again the memory will be reinstated. Thus, memories are active under at least two conditions: (a) during original learning and (b) during reinstatement. Under both conditions the memories are open to disruption by ECS. Since memories that are not reinstated are least disturbed by ECS, they were believed to be

in a different state, a state of inactivity or passivity. Active memories could be disrupted; inactive memories could not.

This experiment has been essentially replicated by many researchers (although see Dawson & McGaugh, 1969a, for a failure to replicate). Davis and his colleagues were simultaneously reporting a similar finding. Davis and Klinger (1969) extended the interval over which potassium chloride, puromycin, and acetoxycycloheximide could produce amnesia by leaving their subjects in the conditioning chamber. Confinement in the training apparatus extended the effective amnesia interval in experiments by Davis and Hirtzel (1970) and Potts (1971). Schneider and Sherman (1968) reported a similar finding. Meyer and his students (Howard, Glendenning, & Meyer, 1974; Howard & Meyer, 1971; Robbins & Meyer, 1970), using a multiple-choice maze, gave animals three different successive problems, each associated with its characteristic cues. They reported amnesia for problems whose cues were paired with ECS, regardless of the age of the memories, which were frequently 3 weeks old. A similar cue-dependent amnesia has been demonstrated many times (DeVietti & Holliday, 1972; Gordon & Spear, 1973a, 1973b; Lewis & Bregman, 1973; Lewis, Bregman, & Mahan, 1972). Finally, DeVietti and Kirkpatrick (1976) and Gordon (1977b) have shown a typically RA gradient in a cue-dependent amnesia situation, which confirms the inference that time-dependent vulnerability of memory is not uniquely associated with storage. Of course, the time dependency of reactivated memories may be due to a different mechanism than for a new memory, but it is unparsimonious to believe this until data supporting two mechanisms are presented. Gordon (1977a) has shown that the reactivated gradient is shorter than a new gradient, but he does not believe this finding is support for two different mechanisms.

The reactivation situation has also been used to show the kind of memory enhancement that has previously been demonstrated when certain drugs are administered soon after a learning experience. Gordon and Spear (1973b) showed that strychnine sulfate could enhance a well-aged memory if and only if the memory were reactivated immediately prior to drug administration, and Gordon (1977b) has shown that this effect is time dependent. Finally, Landfield, McGaugh, & Tusa (1972) found an electroencephalogram (EEG) Θ wave that appeared immediately following learning, and they interpreted the Θ as an indicator of a memory consolidation process. Nicholas, Galbraith, and Lewis (1976) confirmed their empirical finding but found the Θ to occur also upon reactivation of the memory. They interpreted the Θ as an indicator of memory activity.

Conclusion

All of the data presented in this section argues strongly against the standard two-process sequential model in which STM precedes LTM and is a necessary holding template for the LTM. But there are other forms of a two-process model (see McGaugh & Dawson, 1971). For example, STM and LTM could both be initiated at the onset of learning and could parallel each other until STM drops out, while LTM continues. This is a parallel rather than a sequential two-process theory. The basic point being made here, however, is that memories can be recovered following amnesia, regardless of whether the amnesia is conceived of as a failure of STM, LTM, or the transfer between the two. There are, of course, other conceptions of memory formation than have been considered here, but they are variants on a general theme. The theme is that following an experience, new memories are fragile and will decay unless they are either held by rehearsal in STM or transformed into something more permanent. This transference into LTM takes place typically as a function of time or of time and something else, for example, a nonspecific physiological response, usually adrenergic (Barondes & Cohen, 1968a; Gold & McGaugh, 1975). Various arguments and data have been cited to show the inadequacy of these conceptions of an initially fragile STM or LTM. Both intuitive experience and experimental data

indicate that memories are formed almost instantaneously following an experience and that these memories are relatively permanent, are surprisingly resistant to simply decay, and seem to yield only to forms of interference and competition that affect retrieval.

Several powerful guns have recently fired at the consolidation–storage hypothesis. Weiskrantz and Warrington (1975) say:

> But the lack of evidence for a defect of "consolidation" or long-term "storage" in animals is no longer an embarrassment, because that hypothesis appears to be no longer able to account for the amnesic defect in man. (p. 425)

Meyer and Beattie (1977) state:

> However, the argument that interventions which have time-dependent actions upon newly-formed habits produce their effects because they interfere with labile traces has been tested, and found wanting. The argument that interventions which produce complete and lasting impairments of retention must therefore have interfered with memory formation is not now, nor has it been for almost a decade, worthy of serious belief. (p. 154)

Apparently, memory can be formed within a time span of less than a second, and it is reasonable to believe that this may be typical of most memories. There is presently no reason to believe that a new memory is any more fragile than an established one. A physiological process must be found that accommodates such a brief memory formation time span, and we have already seen that reverberating neural firing is not the answer. The synthesis of new protein also probably does not provide a mechanism for the relative immediate formation of memory. Squire (1975) proposes that under the simplest of circumstances, at least 1 minute is required for the synthesis of protein and its transport to a synaptic site. A longer interval would be required if the prior synthesis of mRNA were necessary. This does not deny a role for protein synthesis and the growth of synaptic knobs (Lynch, Deadwyler, & Cotman, 1973; Rutledge, 1976) as a support for frequently evoked memories, but it does deny that these mechanisms are necessary for the formation of permanent memories.

The possibility that learning is due to changes in synaptic neurotransmission remains strong, but a long time-dependent structural change is not necessarily required for such changes to take place. They can, in fact, be rapid, almost as rapid as the elaboration of chemicals at the synapse or the combination of protein fragments or the addition of a carbohydrate to a neural membrane protein, forming a glycoprotein (Bogoch, 1968, 1973). Kety (1970) has proposed a model that suggests how biogenic amines could participate in the learning process. He proposes that novel or surprising stimuli cause the release of the appropriate biogenic amines throughout the central nervous system and that these amines serve to increase firing probability in neural systems that are active and perhaps decrease activity in others. A specific pattern of neural firing then comes under the command of the environmental events existing at the time. The pattern of neural firing is the memory, and it is reactivated when the stimuli are presented again.

Active—Inactive Memory Distinction

Active memory (AM) is considered as a changing subset of all permanent memories possessed by an organism. At any given time many of the permanent memories, which have the potential for being active, are in a relatively inactive state and have little effect on current behavior. A rat, for example, who has learned a complicated T maze has the potential to perform correctly in that maze even though, at a given moment, it is eating from a trough in a living cage in a room that is different from the one in which the learning occurred. Also, a memory may be active without having an observed effect on current behavior. A rat may be in the start box of the T maze and remain stationary for any one of a number of reasons (e.g., low motivation, sickness) other than the failure to reactivate a memory. Although we speak of active memory (AM) and inactive memory (IM), different stores or locations are not implied; it is doubtful that AM occupies a specific site or sites in the brain. It seems

better at present to conceive of AM as a patterned state of neural firing that is not specifically localized, although different memories that are active undoubtedly reflect different densities of firings in different parts of the brain. It is likely that each evocation of an AM will be slightly different from each other evocation, although there must be considerable similarities, or the memories could never be identified as the same (John, 1972).

In each human, AM is intuitively apparent; "immediate consciousness" is a part of it. In lower animals AM is not intuitively apparent except through anthropomorphic analogy. Positing an entity such as AM for rats is scientifically dangerous and certainly far outside the standard stimulus–response (S–R) tradition. Nevertheless, there are precedents for the application of cognitive concepts to rats and for their experimental manipulation. Tolman (e.g., 1932, 1949) was a biologically oriented psychologist whose use of behavioral-based but cognitive concepts such as "purpose," "cognitive maps," and "memorial lore" makes interesting reading today. Although Tolman did not use the concept of AM, his "vicarious-trial-and-error" (VTE) is instructively similar. For Tolman, VTE was most apparent at a choice point and was evidenced by the back-and-forth movement of a rat's head before it committed itself to one of the alternatives. In Tolman's view, the rat was weighing the alternatives, cognitively trying to arrive at the correct decision. He was able to quantify the VTE to some extent. The amount of VTE was a direct function of the difficulty of the problem. For easy discriminations VTEing occurred during the early trials and dropped out as learning proceded. For more difficult problems there was little early VTEing; the greatest amount of VTEing occurred just before and at the time of the solution to the problem and continued some time after. For the most difficult discrimination, VTEing was never greatly reduced after solution, even with a great amount of overlearning. Apparently, the animal had to continue to weigh alternatives on each trial. It may well be that VTE can be used as one index of AM.

Human Conceptions

The concept of STM as an entry point for new memories and their transfer to LTM goes back at least to James (1890). However, the concept of AM, which is simply an aspect of the total memory process into which memory can both flow from IM and serve as a point of entry for new memories, is, seemingly, new. The first mention of an active–inactive distinction may well have been made by Posner (1967), who proposed further that interference and forgetting could take place in AM. He briefly summarizes an experiment that was negative to the concept of AM as an arena of forgetting, but he developed the conception of AM in more detail later (Posner, 1973). Certainly, as is discussed later, AM as a process in which forgetting occurs needs much more experimental testing.

The distinction between AM and IM also developed through the theorizing of Atkinson and Shriffin. In their earlier treatment (1968) they still held to the standard notion of STM that served only as a point of entry and processing of new learning. In Atkinson and Shriffin (1971), however, they conceived of STM as a processing point for both new learning and for retrieved memory from LTM. For them, AM was the conscious activity of memories, regardless of whether they were old or new. It was the control center for rehearsal, coding, and imagining, for all cognitive activity. This is an important theoretical treatment of memory with a sophisticated discussion of AM.

A similar treatment of AM as the site for the processing of retrieved memories as well as for new learning is that of Craik and Lockhart (1972). They suggested that different levels of processing occurred in AM with the deeper semantic levels laying down more effective and retrievable traces. Baddeley and Hitch (1974) also have conceived of AM (working memory) for both storage and further processing of retrieved memories. They show that several cognitive processes (e.g., free recall) are made more difficult with additional simultaneous memory activity. This is because of the limited capacity of AM, which as the "focus of attention"

can perform only a circumscribed set of processes at one time. Bjork (1975) has presented a similar conception of AM, as have Shiffrin (1976) and Bower (1975), among others. Thus, a concept of AM as a central processor of both new learning and of retrieved memories now exists. It is similar to conscious awareness, attention, and even thinking as far as humans are concerned.

Animal Conceptions

For lower animals, the first distinction between AM and IM apparently was made by Misanin et al. (1968), who showed that rats could be made amnesic for old memories if, they hypothesized, the memories were active at the time of ECS, whereas IMs were relatively immune to the amnesic treatment. This distinction has been explored further by Lewis (1969, 1976), Spear (1976), and by Lett (1978). These theoretical and experimental developments are considered in the next sections.

Entry Into Active Memory

Two kinds of events can be distinguished for AM by their route of entry into AM. First, memories can be created anew from external stimulation and, second, memories may be reactivated later when these stimuli are again present. Because entry into AM as a new memory or reentry as an old one usually entails some processing of the sort discussed later, it is impossible to separate entirely the new entry function from the other, and some overlapping of these functions cannot be avoided.

New Memories

Each stimulus activating a receptor is converted into neural impulses and under normal conditions, occasions brain activity that consists of a representation of the stimulus complex, and that representation is one example of an AM. These representations simultaneously contain information about sensory mode or modes, context, temporal arrangements, color, shape, and other properties and relationships among stimuli. In total, these make up the attributes of memory (Underwood, 1969).

Memory is considered to be active for animals whenever the organism is alert and patterned stimuli impinge on the sensorium. Under these conditions it is assumed that the organism is either learning or retrieving. (See Thistlethwaite, 1951, for a review of the latent learning literature, and see Spear, 1973, for a discussion of the role of the stimulus and the context upon retrieval.) Reinforcement is not necessary for learning, but a reinforcer does serve to focus attention by pointing out to the organism that something specific is to be learned. If there is no reinforcement, they will be learning anyway, but it will be more difficult for the experimenter to discover what has been learned. This also means that a nonlearning control group for those who are searching for the physiological correlations of learning cannot be simply one for which reinforcement is not administered. After the organism has learned, the stimuli that were salient (significant, noticed, reinforced, emphasized) during learning can be presented again, and the memory of the learning will occur. Since the experimenter's notion of what the salient cues are may not also be those of the animal, representation (or reinstatement) of the cues may not always reactivate. A distinction between nominal and functional cues is important.

It would be helpful to determine the simplest possible memory. Learning is frequently considered to be an association of two or more items, stimuli, or events, but it becomes difficult at times even to know when two items are present. If, for example, the stimulus object is a square, the top half of which is one color and the bottom is another color, is the stimulus integral or separable (see, e.g., Blough, 1972; Gardner, 1970; Leith & Mahi, 1977)? Nevertheless, items vary in complexity, and it is possible to conceive of the simplest item along a complexity dimension. This kind of primitive conception will have to do for analytical purposes at present. An item of learning will be the conceptual simple unit. When items are related, an association is said to be formed.

It is assumed here that new simple memories have two important properties, properties that will appear startling to some: (a) They are formed almost instantaneously, and (b) they are relatively permanent. Neither one of these properties can be proved empirically, at least at present. Still, they are not empty properties, for they have consequences that can, at least to some degree, be empirically tested (see Lewis, 1969, 1976; Miller & Springer, 1973).

There are two fundamental sets of data that seem to contradict the notion that memory formation can be almost instantaneous. First is the retrograde amnesia gradient which implies that a newly formed memory becomes less susceptible to disruption over time, which, as we have already shown, requires reinterpretation, and the second is the typical learning curve that implies a gradual improvement over trials.

The learning curve seems to require an incremental process, proceeding bit by bit to an asymptote. But this empirical curve must be separated from the underlying theoretical process causing the curve. Although Hull (1943) assumed underlying incremental strength in habit for the learning curve, Guthrie (1935) did not. Guthrie assumed that learning occurred all at once and immediately whenever a response occurred in the presence of a stimulus. Learning was thus a one-trial affair. The incremental learning curve arose because the stimuli varied from trial to trial, and typically a number of trials were required for the response to become attached to a sufficient number of stimuli. Estes (1950) has formalized this assumption, which remains a common and important one (Bower, 1975). Similar one-experience learning assumptions have been made by those studying amnesia (Irwin, Banuazizi, Kalsner, & Curtis, 1969; Lewis, 1976). Recent treatments of learning (see Bower, 1975) are not concerned with the relationship between a stimulus and a response but with the relationship between a stimulus and the contents of AM. Since the contents of AM are at least as variable as the stimuli, another reason for an incremental learning curve is present, even assuming immediate and permanent learning. The point here is that neither the incremental learning curve nor the decremental amnesia gradient requires a theoretical growth or decay process.

Much learning, of course, involves considerable complexity and many items and therefore requires more experience and more trials than does the simplest learning. Obviously, it will take longer to learn a T maze with 10 choice points than a maze with only 1. Multiple-unit learning requires that each unit and the relationship among the units be learned. Complexities of this type have led biological researchers to employ the simplest types of learning situations possible. Typically, two have been selected: Pavlovian conditioning and single-trial passive avoidance learning. Each of these probably still remains complex, relative to what the simplest possible learning situation could be. Even so, the evidence suggests that an animal can learn quickly that a footshock (FS) has occurred in the passive avoidance situation (Lewis et al., 1968) as shown by its avoidance of the FS location on the next trial. The animal may learn only that an FS has occurred, or it may learn also that the source of the FS was the grids on the floor, something about the intensity and quality of the shock, what happened before the shock, and what happened after the shock, all of which will greatly aid in the retrieval of the memory about FS. Such further learning will take more time than the simple learning that an FS occurred, but each item of learning is assumed to occur rapidly and to be permanent.

Established Memories

Perhaps equal in importance to learning, as a source for AM, although frequently neglected, is IM. It is clear that memories have the potential to return to expression long after original learning. It is argued that all contents in AM share similar properties, that is, a reactivated old memory is similar in many respects to a newly created AM.

When stimuli from original learning impinge on sense organs, and the organism attends to them, perhaps as indexed by the

orienting response, a characteristic pattern of neural firing is reinstated, and in some fashion this reinstated firing represents the memory. This kind of conceptualization is different from a traditional S–R paradigm. Adams and Lewis (1962), for example, in the traditional format, proposed that ECS served as an unconditioned stimulus (US) in the classical conditioning sense and that the conditioned competing response evoked by ECS replaced those that had previously been learned in an avoidance situation. The replacement of the original learning appeared to be an amnesia. This interpretation was soon found to be inadequate for the single-ECS situations to which researchers turned because no evidence of a conditioned convulsion could be detected with only one ECS administration (Paolino, Quartermain, & Miller, 1966). Once freed from the bondage of thinking in terms of traditional peripheral responses, it was possible to think in terms of events and memorial representations. Whereas Adams and Lewis thought of competing responses, and Lewis and Maher (1965) proposed the inhibition of peripheral responses, Misanin et al. (1968), in their cue-dependent amnesia experiment, thought of the inhibition of memories.

Because of the imprecise relationship—to the experimenter—of memories to stimuli and responses, it is not always possible for the experimenter to present the exact cues that will reinstate the memory. Garcia and his colleagues (e.g., Garcia & Koelling, 1966; Garcia, Kovner, & Green, 1970; Garcia, McGowan, Erwin, & Koeuer, 1968) have forcefully illustrated that all stimuli are not equivalent in their ability to initiate memories. Ordinarily, for an experimenter to test successfully for memory, either the associated events had to occur in close temporal contiguity or the animal had to maintain a physical orientation to the stimuli (Grice, 1948; Hunter, 1913; Spence, 1947). But Garcia and his colleagues showed that if the stimulus is a novel taste and the response is illness, then even hours may separate the two and still the rat will avoid the novel stimulus the next time it is presented. This phenomena is difficult to formulate in standard learning terms because of the long time interval between the novel taste and the induced illness. Nor does the concept of preparedness (e.g., Seligman, 1970) provide a satisfactory answer to the basic question: How does the rat bridge the gap between the novel stimulus and the sickness? There are several possibilities:

1. Novel tastes create a pattern of neural firing that endures long enough so that the firing pattern from the illness becomes contiguous with that from the taste, and an association is formed. If so, the taste pattern has to subsist through hours of other experiences and thus many other patterns of firing.
2. Illness evokes past taste sensations and novel tastes are the most salient with illness, and thus there is a contiguity between the memory of taste and the illness.
3. Taste aversions in the rat are a special kind of learning for which the animal is innately prepared, and it is simply outside the ordinary laws of learning.
4. Illness creates a phobic reaction to novel tastes in general (Mitchell, Scott, & Mitchell, 1977).

Data that distinguish among these alternatives are not yet available, but if learning is involved, it is difficult to avoid the necessity of a relative contiguity between the associated events, which means that illness probably reactivates the memory of the novel taste, and the association is formed in AM between the reactivated event and the new event (Lett, 1973, 1978).

In summary, it seems that memories not only enter AM from IM but are produced from the external world in a new state. If so, then a very important question is to what extent are reactivated memories like new memories?

Comparison Between New and Established Memories

It has frequently been shown that the disruption of new memories by amnesic agents is time dependent, producing the RA gradient. DeVietti and Kirkpatrick (1976) showed a similar time dependency for reactivated memories, as has Gordon (1977a, 1977b), although Gordon found the effective gradient

shorter for the reactivated memory than for the new one. Because gradients have been found to be so tremendously variable (see Chorover, 1976) even for new memories, this difference is probably not significant. Time-dependent gradients have been produced for reactivated memories by electrical stimulation of the brain through implanted electrodes (DeVietti & Kirkpatrick, 1976), by strychnine sulphate (Gordon, 1977b), and by other competing memories (Gordon & Spear, 1973b). An enhancement gradient for a reactivated memory has also been reported by DeVietti, Conger, and Kirkpatrick (1977).

A retrieved memory may be different from what it was during original learning because some part of it may be obscured due to competition and interference, or it may have become a part of a different memory complex from when it entered memory. Because memories are dynamic, it is unlikely that a retrieved memory will ever be identical to the original, and the very act of retrieval will produce a change. It is also likely that there will always remain enough of this original memory in what is retrieved for the two to be recognizably similar.

As suggested, the process of retrieval itself has an effect on the memory, but it is far from clear what this effect is. Cherkin (1970) has argued that retrieval amounts to additional learning and that the effect of a reminder cue is the same as the effect of an original learning trial. The effects of reactivation on the memory have still to be worked out in detail, but sufficient data exist which show that a learning trial and reinstatement or reactivation trial are not the same (Lewis & Nicholas, 1973; Gordon & Spear, 1973a). Reinstatement is the presentation of the cues that were present during learning but without a reinforcer. Clearly, this is the experimental operation for extinction as well as reinstatement, and extinction is not an additional learning trial. There are other differences between the two, however. For extinction, many trials are repeated with a fairly short intertrial interval, and response decrement increases over trials. For reinstatement, typically, only one trial is given, or if two or three trials are given (Spear & Parsons, 1976), they are widely distributed. It is probable that similar memorial processes are involved for both procedures, but there is a difference in their consequences. In the case of extinction, the successive failures to reinforce indicate that the previously reinforced cues and the associated behavior are no longer significant. Orienting and other alerting behavior are reduced. For reinstatement, presentation of cues without reinforcement is unexpected, producing orienting and rehearsal. The status of the cues as indicators of reinforcement is indeterminate. Also, because reinstatement usually occurs at a long interval following the last learning trial, there is reason to suppose that the memory has been degraded to some extent at the time of the representation of the cues. The degradation can be a function of the stimulus change and memory interference that inevitably occur with time (Campbell & Jaynes, 1966), or it can be due to experimental procedures such as the administration of an amnesic agent.

A first guess is that reactivation has a much stronger effect, at least in multitrial situations, than does a single additional learning trial at the time of learning, that is, a memory return from reactivation following forgetting or amnesia is much more dramatic than the administration of an additional trial during learning (Campbell & Jaynes, 1966; Lewis & Nicholas, 1973; Spear & Parsons, 1976). This suggests that the strong reactivation effect is somehow a function of the partial memory degradation. There is probably a definitional problem in distinguishing reactivation from the effects of distributed learning, although both could be on the same dimension as the beneficial effects of distributed practice (Hill & Spear, 1962; Hintzman, 1974) due to the recovery from the memory degradation that occurs during the intertrial interval.

Processing in Active Memory

In this section some of the processing operations performed on both old and new memories in AM are discussed. Since some processing necessarily occurs both when new

memories are formed and when established memories reenter AM, process similarities are inevitable.

There are four functions of AM that are tentatively defined as follows: (a) to register new inputs, to note that an event has occurred; (b) to associate two or more new inputs to each other, as illustrated by classical conditioning, the first phase of sensory preconditioning (Brogden, 1939), and when "one thing leads to another" (Tolman, 1949) as in latent learning; (c) to associate new learning with already established and reactivated memories. It is assumed that when the established memory is reactivated in AM simultaneously with the learning, an association is formed. The second phase of sensory preconditioning is an illustration of this process. The first conditioned stimulus (CS_1) is paired with the second (CS_2) a number of times, and an association is established (first phase). The CS_2 is then paired with a US (second phase), bringing about an association of the US with the established memory of CS_1 and CS_2. Of course, the degree of association and coding will vary with the different components. A more common example of an association between a new and an established memory is that of secondary reinforcement. CS_1 is first paired with a US. Then the established properties of CS_1 are paired with a new stimulus CS_2, producing a CS_1–CS_2 association; and (d) to associate established memories with other established memories. This occurs when two old memories are reactivated simultaneously (Hearst & Peterson, 1973; Solomon & Turner, 1962). Such studies are commonly performed to show the effect of classical conditioning on instrumental responding and to illustrate how two established memories can affect each other even though they do not share a common response.

AM Functions 1 and 2 have been the object of much laboratory research, but Functions 3 and 4 have not received the attention they deserve, and they are probably more interesting. They involve the study of memory structures and systems. Certainly these functions will soon attract the attention of inventive researchers.

Postresponse Events

In traditional S–R theory a learning trial was considered completed when the designated response was over and reinforcement was administered. It is now known that there are post response events that are extremely important to the later use of the memory. Duncan (1949) made this point in his classical study of amnesia when he demonstrated that a gradient was a function of the time interval from the termination of the learned response to the administration of ECS. Lewis and his colleagues (see Lewis et al., 1968) have long argued that the interval immediately following a learning trial is used by the organism for cognitive processes that aid in the retrieval of the memory. Tolman (1949) gave an illustration of a postresponse cognitive process when he described an experiment by Hudson who found no avoidance learning to electric shock if the apparatus cues surrounding the shock were removed immediately following treatment. If, however, the cue remained so that the animal could look back "to see what happened," as Tolman put it, it readily learned to avoid. Essential aspects of this study have been replicated by Keith-Lucas and Guttman (1975).

Wagner, Rudy, and Whitlow (1973) showed that if an unexpected stimulus was presented following a learning trial, retention was impeded, and the interference was a function of the time interval between the learning experience and the unexpected stimulus. They believed that adequate learning required a posttrial rehearsal process that was prevented by the unexpected stimulus. Similar data have been presented by Terry and Wagner (1975) and Miller, Misanin, and Lewis (1969). Also for humans, Waugh and Norman (1965) showed that any new item can displace an earlier one if it is unexpected but that there was no interference from highly predictable and redundant items. Bartus and Johnson (see Bartus & LeVere, 1976), with monkey subjects, found that the interference during postresponse processing was a function of the similarity of the postresponse stimulus to the relevant learning stimulus, indicating a retroactive interference

phenomenon. These studies emphasize the importance of postresponse processing for adequate retrieval to occur. If this process is interrupted by surprising stimuli, by stimuli that make it difficult to discriminate the important learning stimuli, or by the electrical stimulation of the brain, retrieval is interfered with.

What is the nature of the postresponse rehearsal process? It would be convenient to conceive of it as a sort of perseveration of the original input or a sort of continuing repetition. Although something of this sort may occur, it is also likely that a more active and cognitive activity takes place. Lewis (1976) hypothesized two phases of learning. First, the organism registers that the event has happened—an FS, the intrusion of another organism, and so forth. Second, there is a form of interpretation of the event, a relating of the new to the established, that is, that it was painful and came from the floor or that it was female and in heat, and so forth. It is this elaboration, following the initial registration of the occurrence of the event, that occupies the postresponse time. (See Bower, 1972, 1975; Everett & Corson, 1973; and Greeno, 1970, for a possibly similar notion.) This is certainly what Tulving (1970) had in mind when he said, referring to humans:

> When a to-be-remembered unit is stored, some ancillary information about it is also stored with it. The storage of this ancillary information represents what is referred to as "coding." When some of this ancillary information (or the "code" of the to-be-remembered unit) is available at the time of attempted recall, the code serves as a retrieval cue. (p. 8)

Sara, David-Remacle, and Lefevre (1975) also argue for a "core" memory that is blocked by ECS and that can be elaborated by further experience, returning the core memory to expression. Azmitia, McEwen, and Quartermain (1972) found no amnesia if the subjects recovered from ECS in the training environment. They also argue for a core memory that is not disrupted by ECS and for a further learning stage, "which may involve integration of the experimental cues associated with the core trace with the animal's existing memory repertoire of accessible experiences" (p. 855). It may also be similar to the distinction between item and order information (Murdock, 1974). The animal is trying to "make sense" out of what happened, to relate the event to the remainder of its experience. The distinction is perhaps also similar to that between the data and the address for the data in computer language. If no address is given for the data, their retrieval will be difficult indeed.

If the target event is commonplace and has been repeated many times, then the memory elaboration need not occur, other than to record that the event has happened again. The event is immediately recognized as familiar and readily fits the memories (event representations) already in existence. If the target event is surprising or unexpected, the rehearsal process is engaged to interpret the event, to fit it into an existing memory system, or to recognize and differentiate the new event from other events. These elaborative processes (rehearsal) take place in AM, and since one of the important characteristics of AM is its severely limited capacity, processing of other temporally near events must be curtailed, and therefore their retrieval will be reduced (Wagner et al., 1973). These postresponse processes involve new and rapidly formed memories that serve the purpose of aiding the retrieval of the memory of the target event. The more the event is distinctive and becomes part of an already existing memory system, the better is its retrieval (see Lewis, 1976). If postresponse stimuli are presented that are similar to the learning stimuli, retrieval is made difficult through interference (Bartus & Levere, 1976).

Preresponse Events

It is proposed that conditions existing prior to the target event also have an effect on memory processing. Lewis et al. (1968) showed that animals familiarized with the apparatus in which they were to receive FS and immediate ECS demonstrated reduced amnesia. They reasoned that this was because the properties and location of the FS were easy to distinguish in the familiarized en-

vironment, and the meaningful coding of the FS was simple and took less than .5 sec (Lewis, 1976). If an animal already knows "what leads to what" (Tolman, 1932) in an environment, the introduction of a new salient or biologically relevant stimulus is quickly assimilated (automatic search) into the "cognitive map" of the environment, leading to appropriate behavior. Lubow, Rifkin, and Alek (1976) present interesting data on this effect. They show easy learning when a novel stimulus is used in a familiar environment and when a familiar stimulus is used in a novel environment as compared to using a novel stimulus in a novel environment or a familiar stimulus in a familiar environment. This suggests that a familiar stimulus will not result in amnesia in a new environment.

Whether or not animals learn without reinforcement is no longer an issue; they do. Latent learning is discussed here as a form of familiarization with the environment that facilitates further learning when the experimental stimulus is introduced—either the reinforcer (Blodgett, 1929) or the FS (Lewis et al., 1968). The preresponse familiarization builds a cognitive structure into which the new event is readily assimilated. The importance of these preresponse events is further illustrated by Mitchell et al. (1977) who found that a long-delayed poison-induced aversion to novel visual stimuli in rats can be readily obtained if the animals have had extensive familiarization (habituation) with the environment prior to the introduction of the novel stimulus. Without the familiarization, visual stimuli do not readily become capable of eliciting delayed aversions.

The notion that prior familiarization facilitates new learning in the familiarized situation has human counterparts. Shiffrin (1976), who also takes the point of view that forgetting is a retrieval problem, discusses the limitations on retrieval posed by the limited capacities of AM. He says that search in AM can be either automatic or controlled.

> Automatic search occurs when a stimulus or set of stimuli is sufficiently trained with respect to a given background (or distractor stimuli) that it becomes associated with an automatic attention response that will cause the given stimulus to be searched or considered first, before competing stimuli. (p. 220)

Again, he says:

> Automatic search is facilitated by targets having distinctive simple general physical characteristics relative to the background (distinctive color, shape, orientation, location, etc.). In addition, automatic search can develop if any set of targets is trained sufficiently long with respect to a given background. (p. 224)

A similar notion has been presented by Sperber, Greenfield, and House (1973), who argue that an adequate representation or effective code of an item is more difficult to form when the item is unfamiliar than when it is familiar and already coded.

In summary, the characteristics of AM, particularly its limitations on the number of items that can be active at any time, have a great effect on what is retrieved. New learning will be easily retrieved if it occurs in an environment that is familiar and that provides, through existing memory representations of the environment, a memory context into which the new event may fit. If a new stimulus is introduced into a less familiar environment, more time will be required to fit the new learning into some existing memory context. This may be better conceived of as a coding process rather than rehearsal, which implies a mere repetition or holding of memory items. Tests of this distinction can be made by manipulating both prelearning and postlearning environments.

Loss of Accessibility to AM

Perceptual Stimuli

Since stimuli are almost always impinging on receptors, there is an immense amount of incoming information. Each head movement brings new stimulation and new information. It is clear that a great part of this new information, if it is different in any respect from memories, is almost immediately lost, and a basic question concerns the mechanism of the loss. There are two primary alternatives:

1. The consolidation process, which maintains that new information either fades or is open to destruction for a period of time following its formation and that incoming information destroys current newly formed old information (McGaugh, 1966; McGaugh & Gold, 1976; Müller & Pilzecker, 1900). At the receptor image level, there is a basis for fading images (Sternberg, 1966), but this notion has been rejected previously in this article as the explanation for the forgetting of memories.

2. The interference hypothesis, which maintains that the new items interfere with each other based on various properties such as similarity and the difficulty in discriminating among many similar items as the organism moves through the environment. This seems a reasonable explanation even for the forgetting of the multitude of perceptual items and is identical to the retrieval hypothesis.

Active Memory Forgetting

Until 1969, all studies of experimental amnesia had at least three properties in common. One was the presentation of cues for new learning, the second was the administration of a reinforcer, usually negative, and the third was the administration of the amnesic agent. Misanin et al. (1968) departed from the usual procedure by replacing the cues for new learning with cues for established memories that they paired with ECS and produced a memory decrement. They also presented ECS without the cue and obtained no memory decrement. Two interpretations of their data are plausible. One is that the ECS reduced the evocative power of the stimulus with which it was paired so that it was not, on a test, followed by the memory, a form of stimulus inhibition; the other is that the memory (response) was blocked by the ECS. The experimenters preferred the second interpretation and concluded that ECS worked only on memories that were active and that memory age was irrelevant. The conclusion is that AMs, or those in transition between inactivity and activity, are open to disruption by amnesic agents, and IMs are not.

It is an interesting speculation that the AM disruption is not limited to amnesic agents. Perhaps AMs are open to decrements due to all forgetting agents (Lewis, 1969). Perhaps IMs are protected from forgetting loss, the loss occurring only with memory activity.

Only a little information relevant to this hypothesis can be found in the traditional animal learning literature because insufficient attention has been devoted to the study of forgetting. Spear (1976), whose own work is an exception, could find no evidence that Pavlov, for example, ever manipulated the retention interval. Students of animal learning traditionally did not use the concept of memory, and the word *forgetting* was almost totally absent from their vocabularies. "Response elimination" was their approximation of this problem, and most of the procedures were those of extinction. If a learned response was repetitively evoked without reinforcement, it would eventually extinguish. This, however, was more likely a form of discrimination learning (discriminating nonreinforced from reinforced conditions) rather than forgetting, which operationally involves a retention interval between the end of learning and the test.

The paucity of animal data is a contrast to that existing for humans. Without going into the wealth of detail existing in the study of human forgetting, an attempt is made to summarize the most important determiners of forgetting in human memories, with the view of determining the possible relevance of this body of information to the kind of AM forgetting conceptualized here.

First are cue and context changes (Tulving, 1972). Memories are formed in a stimulus environment, and these stimuli can later serve to reactive the memories. To the extent that the cues and context change, forgetting will occur, that is, memories will not be evoked. Since cues are always changing, there will be a greater cue change with time, and thus forgetting increases over time. Second, forgetting is also caused by interference, which had traditionally been viewed as a phenomenon of retrieval (Peterson, 1977), even though the interfering material

was learned close to original learning and long before the recall test. Interference basically means that the subject does not distinguish adequately the occasion for remembering X rather than Y. This failure to distinguish is based on the similarity of the learned material to the interpolated material. For example, if a subject first learns an association between A and B and then learns an association between A and C, the two associations will interfere with each other when A is presented at recall. The more similar the items (or lists), the greater will be the interference. Thus, similarity is the keystone of forgetting through interference. It may be that the subject will remember the item but will be confused about the appropriate place to use the item. In the laboratory, this is a failure to make a "list differentiation." Coding serves to increase the distinctiveness of the learned material and thus facilitates retrieval.

In summary, human forgetting is considered to have two primary causes: (a) a change in the stimulus conditions from those that were present at the time of learning. This change can be either external or internal to the organism; and (b) interference due to the learning of similar material.

Can these basic principles of forgetting be integrated with those already discussed and applied to the exit of memories from AM for lower animals? The application is indeed speculative and must be treated with great caution, but Spear (1971, 1976, 1978) has shown that such an application can be fruitful.

First, there are cue changes. An active organism is being constantly bombarded with stimuli, many of which are registered in AM (and which simultaneously have a representation in IM, that is, again, that memories are formed quickly and are permanent). Representations may be held in AM for varying lengths of time. Familiar and expected representations come and go with great rapidity. They already fit into existing memory systems, and little new processing is needed. Perhaps the only new learning that occurs upon the appearance of familiar stimuli is that an old item has occurred again. Unexpected and surprising representations are held for a longer period of time. During this time coding occurs, one of whose purposes is to make the representation retrievable by fitting (association, further learning, coding) it into an existing memory assembly. In a sense this coding makes the representation distinctive, for the representation fits into a particular memory assembly because of its similarities with and differences from other memories. If a representation is not adequately coded, its retrievability will be greatly reduced. This coding (or rehearsal) takes time, during which the organism cannot be attending to other stimuli, or there will be interference and retrievability will be reduced.

A novel stimulus evokes the orienting reflex (Pavlov, 1927) that ordinarily produces a focusing on the new stimulus and therefore protects it from interference during the rehearsal or coding. Another novel stimulus registering during this period that requires coding may preempt the rehearsal process and reduce the retrievability of the first representation (Wagner et al., 1973). The closer the distractor stimulus appears in time to the first stimulus, the greater will be the interference and the less the retrievability. Here, the reference is to the interference between new memories in which inadequate processing is prevented by the preemption of the limited capacity AM. The first stimulus representation should still be capable of retrieval if an appropriate probe is used.

One of the principal points of the present interpretation is that AMs are particularly open to interference. This may be at least one of the reasons that the A-B, A-C paradigm produces interference. The A of the A-C learning component reactivates the A-B memory. When A-B and A-C are both active, the interference occurs. An A-B, X-B sequence would produce little interference because the memories are not concurrently active. Immediately after presentation, paired associates are vulnerable to forgetting, and the loss is geometric. Perhaps forgetting will not occur unless memories are reactivated in a context that produces interference. The time-dependent interference in the Peterson and Peterson

(1959) paradigm suggests this. Gordon and Spear (1973a) have shown an AM interference using the cue-dependent amnesia paradigm. After one memory was well learned, they presented the cue for this memory while simultaneously evoking a competing memory. Considerable forgetting ensued under these circumstances, but there was no forgetting if the established memory was inactive. This is a landmark study in showing that AMs interfere with each other, but that an AM does not interfere with an IM. More recently Gordon (1977a) and Gordon and Feldman (1978) have shown that the reinstatement of a passive avoidance memory will interfere with the retention of a new active avoidance memory.

ECS as Interference

There is a growing body of evidence that ECS blocks AMs regardless of whether they are old or new, but IMs are not disturbed. Generalizing this finding, it has been suggested that AMs may be open to disruption by normal forgetting agents, particularly by similar AMs (Gordon & Spear, 1973a). The similarity between normal forgetting and forgetting due to ECS is difficult to see, but it probably lies in the neural activity that must accompany memory activation. Each AM, whether new or established, must involve a distinctive pattern of neural firing that (a) represents an environmental or other event and (b) will be repeated when the event is repeated. The pattern probably involves a characteristic frequency of firing for single neurons as well as a characteristic assemblage of neurons.

After reviewing a great deal of EEG data, John (1972) concluded that

> the evidence which has been presented indicates that when a specific memory is retrieved, a temporal pattern of electrical activity peculiar to that memory is released in numerous regions of the brain. To that released set of waveshapes corresponds the average firing pattern of ensembles of neurons diffusely distributed throughout these widespread anatomical domains. . . . This suggests that during retrieval of a particular memory, a unique and invariant temporal pattern of coherence occurs in the neural discharges averaged across a spatially distributed and diffuse ensemble of neurons, in which the variable activity of an individual neuron is significant primarily insofar as it contributes to the statistics of the population. (p. 862)

It is assumed that similar memories have similar components of neural firing. It is further assumed that when two similar memories are simultaneously active, there is competition and interference between their firing patterns. That is simply to say, two different patterns involving the same neurons, at least to some degree, cannot be firing simultaneously without interference between the two patterns. *The occurrence of one inhibits or blocks the other.* This is the major assumption. When overlapping neural firing patterns are evoked simultaneously, they interfere with each other and reduce the probability that either will fire again under similar circumstances. We know that similar responses and similar memories compete with each other, and we know that memories and responses are based on neural activities. All that is added here is that memory competition is based on neural competition, and that similarity is an important determiner of the competition. In experimental amnesia, the presentation of the learning stimulus activates a memory and its characteristic pattern of neural firing. While the memory pattern is active, another pattern is created by the ECS, which effectively interferes with or blocks the activated memory pattern.

Admittedly, this is highly speculative and is based on little physiological data. But it is not more speculative or based on less data than a theory which maintains that a learning event establishes a physiological structure that is fragile and open to disruption for a period of time and that amnesic agents serve to destroy this process.

The interference-retrieval hypothesis is far from implausible. The basic assumptions are as follows: (a) An active memory requires neural firing, (b) the pattern of neural firing is characteristic of that memory, (c) similar memories share similar neural firing components, (d) similar, but different, memories and neural firing patterns that are active at the same time interfere with each other,

(e) interference between neural firing patterns results in forgetting, and (f) the interference results not in a memory destruction but a blocking.

Conclusion

A point of view has been presented here in an area of investigation that has many perplexities and complexities. Certainly, there are pockets of data that do not, at the moment, fit tidily into the current conception, but the emphasis on retrieval failure as the source of forgetting in psychobiology has been growing and making increasing inroads on the traditional storage-failure approach. (See Spear's excellent new book, 1978.) Retrieval failure is more consonant with the important theorizing of human cognitive psychology and, at the moment, seems to comprehend a large segment of the psychobiological data, and the distinction between AM and IM affords a cohesive framework for conceptualizing this data. The major lesson for psychobiologists is that they would profit from turning a greater amount of their research efforts to the study of retrieval mechanisms and that they should consider the implications for physiological study of a learning engram that is formed permanently in less than a second.

An interesting point that remains to be considered is the distinction, if any, remaining between a consolidation-storage point of view and a retrieval point of view. Without doubt the distinction is becoming blurred. The consolidation-storage approach has moved from conceptualizing a long-delayed fixing of structure produced by learning (Gold & McGaugh, 1975; McGaugh, 1966) to the position of Bloch (1976), who says that consolidation "would be better named the phase of information processing" (p. 583) or Cherkin (1970), who says that anything occurring soon after acquisition is part of the consolidation process. This conceptualization of consolidation is similar to the present approach and, as Bloch points out, requires brain activities that can be prevented or enhanced.

There nevertheless remain several important distinctions between the two. One of these is empirical and the others are conceptual. The empirical distinction concerns the consolidation-storage approach, which argues that the various brain manipulations producing forgetting do so either by eliminating the physical trace of learning (McGaugh, 1966) or by reducing it below some threshold of expression (Cherkin, 1972).

If reminder stimuli reinstate a memory, as they clearly do, then the amnesia or forgetting cannot have been due to insufficient storage. As has already been reviewed, the storage theorists argue that the reminder stimulus (a) is not effective if amnesia is complete and (b) serves simply as another learning trial if amnesia is not complete. Both of these arguments have been rebutted here and elsewhere (Miller & Springer, 1973, 1974; Spear, 1973; Spear & Parsons, 1976). Reminder has been shown following complete amnesia, and reinstatement has a greater effect than a single additional learning trial. The conclusion drawn here is that ECS and other forms of brain intervention block the retrieval of memory, whether old or new, rather than its storage. This is the interpretation that is most consistent with existing data. On this point differences do remain between a storage and retrieval point of view.

The distinction between the two has largely been lost at the conceptual level when the consolidation-storage approach is viewed as a form of information processing. Information processing here has been treated as a form of coding and elaboration of already stored memories. This elaboration is additional learning and it aids in the retrieval of previous learning. In the current conception, a subject learns A (that FS occurred), then he learns B (that it came through the grid bars), then he learns C and D, and so forth, which are new items of learning that give meaning to the total, including A, and that aid in retrieval. Amnesic agents prevent this further processing, and they also block (interfere with) the later expression of A or of any learning that has occurred up to the point of the amnesic agent as long as that new learning is still in AM. If this is now what consolidation means, then it is to that extent a retrieval theory.

Interactions, Partial Interactions, and Interaction Contrasts in the Analysis of Variance

Robert J. Boik
Pepperdine University

A two-step framework for the interpretation of significant two-treatment interactions is proposed. First, a contrast between the means of one treatment is estimated separately at each level of the second treatment. A partial interaction test tests the hypothesis that the variabiliy among these contrasts is zero. The second step consists of computing a difference between the separately estimated contrasts. An interaction contrast test tests the hypothesis that this difference is zero. The familywise Type I error rate can be controlled at alpha by employing Gabriel's simultaneous test procedure for partial interaction tests and Scheffé's method for interaction contrast tests.

Recently, an issue has arisen concerning a posteriori tests after detection of a significant interaction in the analysis of variance. Marascuilo and Levin (1970) and Levin and Marascuilo (1972) have criticized the use of simple effects tests in which the means within a single row or column of the data matrix are compared. Their basic criticism is that the null hypotheses tested by simple effects tests are not coherent with the null hypothesis tested by the a priori omnibus interaction test. To maintain a coherent analysis, Marascuilo and Levin recommended testing interaction contrasts after detection of a significant interaction.

In commenting on the approach of Marascuilo and Levin (1970), Games (1973) argued that although interaction contrasts are coherent with the omnibus interaction test, these contrasts do not easily lend themselves to meaningful behavioral interpretations. Consequently, Games recommended performing simple effects tests. Levin and Marascuilo (1973) replied by emphasizing the flexibility of the interaction contrast approach. Thus far, there is little evidence that the issue has been resolved (Marascuilo & Levin, 1976; Games Note 1).

This article neither attempts to resolve nor necessarily even to clarify the issue. The question of whether interaction contrasts should be tested must ultimately be answered by each individual researcher. Rather, the article attempts to present a conceptual framework for testing interaction contrasts, should the researcher decide to do so. Interaction contrasts will not be tested unless they can be readily interpreted by the researcher. It is hoped that this the conceptual framework presented in this article will increase the meaningfulness of interaction contrasts.

Hypothetical Data

The means for a set of hypothetical data are presented in Table 1. Each of 72 biology students complaining of a severe fear of blood (hemophobia) was randomly assigned to one of the 12 cells with the restriction that 6 students be assigned per cell. Treatment A represents three types of fear reduction therapy. Subjects in the first level of Treatment A served as the control group and did not participate in any therapy. Subjects in the second and third levels of Treatment A participated in therapies denoted as a_2 and respectively. Treatment B represents four doses of an antianxiety medication. The dose level increases from b_1 (placebo) to b_4 (ma

A version of this article was presented at the meeting of the Western Psychological Association, San Francisco, April 1978.

Requests for reprints should be sent to Robert J. Boik, Department of Applied Statistics, School of Business, Temple University, Philadelphia, Pennsylvania 19122.

imum dose). Therapy sessions occurred while the subjects were under the influence of the drug. The dependent variable is the magnitude of the electrodermal response (in arbitrary units) when subjects were exposed to blood. Subjects were not under the influence of the drug when the electrodermal response was measured.

The ANOVA summary table is presented in Table 2. Both treatments and the interaction are significant at the .01 level. The strength of the treatments and interaction as measured by ω^2 (see Kirk, 1968, for a description) is as follows: $\omega^2{}_A = .33$, $\omega^2{}_B = .31$, and $\omega^2{}_{AB} = .17$. The strength of association for the treatments and interaction combined is $\omega^2 = .81$. Thus the therapies used, the drug doses selected, and the interaction between the two treatments do account for a substantial portion of the variability among the electrodermal response scores (however, see Glass & Hakstian, 1969, for a cautionary note on the use of ω^2).

Treatment Contrasts

A contrast among the p levels of Treatment A is denoted by A_t and defined as

$$A_t = \sum_{1}^{p} c_i \mu_{i.}, \tag{1a}$$

where t = a subscript of arbitrary value used to distinguish one Treatment A contrast from another; c_i = the coefficient of the contrast associated with the ith level of Treatment A. The p coefficients are subject to the restriction

$$\sum_{1}^{p} c_i = 0. ,$$

Table 1
Hypothetical Means for a 3 × 4 Factorial Design in Which Each Cell Mean Is Based on Six Observations

Treatment A	Treatment B b_1	b_2	b_3	b_4	Row M
a_1	50.2	47.5	46.0	47.9	47.9
a_2	49.9	38.2	28.5	19.0	33.9
a_3	45.7	39.1	36.5	32.7	38.5
Column M	48.6	41.6	37.0	33.2	40.1

Table 2
Summary of Analysis of Variance

Source	*SS*	*df*	*MS*	*F*
Treatment A	2,444.16	2	1,222.08	63.82
Treatment B	2,370.96	3	970.32	41.27
Treatment A × Treatment B	1,376.40	6	229.50	11.98
Within cell	1,149.00	60	19.15	

Note. Total *SS*s = 7,340.52, total *df*s = 71. All *F*s are significant at $p \leq .01$.

and $\mu_{i.}$ = the population mean of the ith level of Treatment A averaged across all levels of Treatment B. The estimate of A_t is denoted by $\hat{A}_t$ and defined as

$$\hat{A}_t = \sum_{1}^{p} c_i M_{i.}\ , \tag{1b}$$

where $M_{i.}$ = the sample mean of the ith level of Treatment A averaged across all levels of Treatment B. The $p \times 1$ vector of coefficients (i.e., the p c_is) associated with A_t and $\hat{A}_t$ is denoted by $\mathbf{A}_t$. For example, the coefficient vectors associated with the three pairwise Treatment A contrasts are $\mathbf{A}'_1 = (1\ -1\ 0)$, $\mathbf{A}'_2 = (1\ 0\ -1)$, and $\mathbf{A}'_3 = (0\ 1\ -1)$. From Equation 1b, the estimates of the pairwise contrasts are $\hat{A}_1 = 14.0$, $\hat{A}_2 = 9.4$, and $\hat{A}_3 = -4.6$.

The sum of squares accounted for by a Treatment A contrast is given by

$$SS_{A_t} = \frac{nq\hat{A}_t^2}{\sum_{1}^{p} c_i^2}, \tag{2}$$

where q is equal to the number of levels of B. From Equation 2, the sums of squares of the three pairwise contrasts are $SS_{A_1} = 2352.00$, $SS_{A_2} = 1060.32$, and $SS_{A_3} = 253.92$. The corresponding 1 and 60 degrees of freedom F ratios are $F_{A_1} = 2352.00/19.15 = 122.82$, $F_{A_2} = 1060.32/19.15 = 55.37$, and $F_{A_3} = 253.92/19.15 = 13.26$. The critical F using Scheffé's (1953) method and $\alpha = .01$ is $S = 2 \cdot F(2, 60) = 2(4.98) = 9.96$. It is concluded that both therapies (a_2 and a_3) resulted in a smaller electrodermal response (EDR) than the control group and that therapy a_2 resulted in a smaller EDR than therapy a_3.

A contrast between the q levels of Treatment

B is denoted by B_u and defined as

$$B_u = \sum_1^q c_j \mu_{\cdot j}\,, \tag{3a}$$

where u = a subscript of arbitrary value used to distinguish one Treatment B contrast from another, and c_j = the coefficient of the contrast associated with the jth level of Treatment B. The q coefficients are subject to the restriction

$$\sum_1^q c_j = 0.$$

$\mu_{\cdot j}$ = the population mean of the jth level of Treatment B averaged across all levels of Treatment A. The estimate of B_u is denoted by $\hat{B}_u$ and defined as

$$\hat{B}_u = \sum_1^q c_j M_{\cdot j}\,, \tag{3b}$$

where $M_{\cdot j}$ = the sample mean of the jth level of Treatment B averaged across all levels of Treatment A. The $q \times 1$ vector of coefficients associated with B_u and $\hat{B}_u$ is denoted by $\mathbf{B}_u$. For example, the coefficient vector associated with the contrast between the placebo dose (b_1) condition and the three nonzero dose conditions is $\mathbf{B}'_1 = (3\ -1\ -1\ -1)$. The contrast estimate from Equation 3b, is $\hat{B}_1 = 34.0$.

The sum of squares accounted for by a Treatment B contrast is given by

$$SS_{B_u} = \frac{np\hat{B}_u^2}{\sum_1^q c_j^2}\,. \tag{4}$$

For example, the sum of squares of the B_1 contrast is $SS_{B_1} = 1734.00$. The F ratio is $F_{B_1} = 1724.00/19.5 = 90.55$. Since the observed F is larger than the Scheffé value, $S = 3F(3, 60) = 3(4.13) = 12.39$, $\alpha = .01$, it is concluded that on the average, the EDR is smaller under the three drug conditions than under the placebo condition.

Partial Interactions and Interaction Contrasts

Often treatment contrasts such as A_1, A_2, A_3, and B_1 are not tested when the Treatment A $\times$ Treatment B interaction is significant. This reflects the commonly held belief that a significant interaction renders treatment contrasts meaningless. Fortunately, this is not the case.

Let us define $A_{t(j)}$ as a simple Treatment A contrast at the jth level of Treatment B. That is,

$$A_{t(j)} = \sum_1^p c_i \mu_{ij}\,, \tag{5a}$$

where μ_{ij} = the population mean of the ith level of Treatment A at the jth level of Treatment B. The simple treatment contrast $A_{t(j)}$ is estimated by $\hat{A}_{t(j)}$, where

$$\hat{A}_{t(j)} = \sum_1^p c_i M_{ij}\,, \tag{5b}$$

and M_{ij} = the sample mean of the ith level of Treatment A at the jth level of Treatment B. For example, from Equation 5b, the estimates of the $A_{2(j)}$ simple treatment contrast are

$$\hat{A}_{2(1)} = 4.50,$$
$$\hat{A}_{2(2)} = 8.40,$$
$$\hat{A}_{2(3)} = 9.5,$$

and

$$\hat{A}_{2(4)} = 15.2.$$

The simple effects procedure described by Games (1973) consists of individually testing the four simple treatment contrasts while ignoring the A_2 treatment contrast itself. However, the significant Treatment A $\times$ Treatment B interaction does not necessarily indicate heterogeneity among the q $A_{2(j)}$ simple contrasts. If the observed variability among the four $\hat{A}_{2(j)}$ simple contrast estimates can be attributed to experimental error, then the A_2 treatment contrast can be interpreted without regard for the significant Treatment A $\times$ Treatment B interaction. The test of homogeneity among the four $A_{2(j)}$ simple contrasts represents a partial test of this interaction. Let us denote this source of variation as the interaction between the A_2 contrast and Treatment B or, more simply the A_2B partial interaction.

The sum of squares for an A_tB partial interaction can be obtained from

$$SS_{A_t\mathrm{B}} = n\{\sum_1^q \hat{A}^2_{t(j)} - [\sum_1^q \hat{A}_{t(j)}]^2/q\}\Big/\sum_1^p c_i^2\,.$$

Equation 6 represents a modification of the familiar computational formula for a sum of squares:

$$SS = \sum_1^n X_m^2 - (\sum_1^n X_m)^2/n.$$

The simple contrast estimates have been substituted for the raw scores; the equation has been divided by

$$\sum_1^p c_i^2$$

to normalize the contrasts; and finally, because each cell mean is based on n observations, the equation has been multiplied by n. The degrees of freedom for the A_tB partial interaction are obtained by multiplying the degrees of freedom of the A_t contrast by the degrees of freedom for Treatment B. That is,

$$df_{A_t\mathrm{B}} = (df_{A_t}) \cdot (df_{\mathrm{B}}). \qquad (7)$$

From Equation 6, the sum of squares of the A_2B partial interaction is $SS_{A_2\mathrm{B}} = 6(412.1 - 37.6^2/4)/2 = 175.98$. The degrees of freedom from Equation 7 are $df_{A_2\mathrm{B}} = (1)(3) = 3$. The mean square and F ratio are therefore $MS_{A_2\mathrm{B}} = 175.98/3 = 58.66$, and $F_{A_2\mathrm{B}} = 58.66/19.15 = 3.06$.

The critical value for the F ratio of an a posteriori partial interaction test cannot be obtained by Scheffé's method unless the partial interaction has only one degree of freedom. However, the simultaneous test procedure (STP) developed by Gabriel (1964, 1969) can be employed. The STP and Scheffé's method are both coherent with the omnibus F test and therefore are coherent with each other. The relationship between Scheffé's method and the STP has been described by Boik (1979). The critical value for an a posteriori ν_3 degrees of freedom partial interaction test is

$$G_{\nu_3} = \nu_1 F(\nu_1, \nu_2)/\nu_3, \qquad (8)$$

where $F(\nu_1, \nu_2)$ = the critical value for the omnibus interaction test. Note that when $\nu_3 = \nu_1$, the critical value is equivalent to that of the omnibus test, and when $\nu_3 = 1$, the critical value is equivalent to that given by Scheffé's method.

For the A_2B partial interaction test, the critical STP value is $G_3 = [6 \cdot F(6, 60)]/3 = (6 \cdot 3.12)/3 = 6.24$, $\alpha = .01$. Since the observed F of 3.06 is less than 6.24, it is concluded that the $A_{2(j)}$ simple contrasts are homogeneous over the q levels of Treatment B. Thus, not only does the a_2 therapy result in a lower EDR than the control group on the average, but in addition, the difference is the same for all four drug levels.

A similar analysis for the A_1 contrast results in a different conclusion. The sample estimates of the four $A_{1(j)}$ simple treatment contrasts are

$$\hat{A}_{1(1)} = .3,$$
$$\hat{A}_{1(2)} = 9.3,$$
$$\hat{A}_{1(3)} = 17.5,$$

and

$$\hat{A}_{1(4)} = 28.9.$$

From Equations 6 and 7, the sum of squares and degrees of freedom for the A_1B partial interaction are $SS_{A_1\mathrm{B}} = 1332.12$, and $df_{A_1\mathrm{B}} = 3$. The mean square and F are therefore $MS_{A_1\mathrm{B}} = 444.04$, and $F_{A_1\mathrm{B}} = 23.19$. Since the observed F is larger than the critical STP value of 6.24, the A_1B partial interaction is judged significant. This indicates that the difference between the control condition and therapy a_2 is not identical for all drug levels. An examination of the $A_{1(j)}$ simple contrast estimates suggests that the difference between the control group and the a_2 therapy group might be larger under the three nonzero drug dose conditions than under the placebo condition. This hypothesis can be tested by means of an interaction contrast.

A product interaction contrast consists of a contrast between simple treatment contrasts. In the previous example, the interaction contrast described consists of the difference between the $A_{1(j)}$ simple contrast under the placebo condition and the average $A_{1(j)}$ simple contrast under the three drug conditions. The Treatment B coefficient vector associated with the interaction contrast is $\mathbf{B}'_1 = (3\ -1\ -1\ -1)$.

Let us denote a product interaction contrast as $A_t B_u$ and define it as

$$A_t B_u = \sum_1^q c_j A_{t(j)}\,, \qquad (9a)$$

where c_j = the jth coefficient in the coefficient vector $\mathbf{B}_u$. The coefficient vector $\mathbf{B}_u$ describes

the contrast between the $A_{t(j)}$ simple treatment contrasts. An A_tB_u interaction contrast is estimated by $\widehat{A_tB_u}$, where

$$\widehat{A_tB_u} = \sum_1^q c_j\hat{A}_{t(j)} . \quad (9b)$$

The sum of squares of a product interaction contrast is computed from

$$SS_{A_tB_u} = \frac{n(\widehat{A_tB_u})^2}{(\sum_1^p c_i^2)\cdot(\sum_1^q c_j^2)}, \quad (10)$$

where c_i = the ith coefficient in the vector $\mathbf{A}_t$, and c_j = the jth coefficient in the vector $\mathbf{B}_u$. The degrees of freedom for a product interaction contrast are equal to

$$df_{A_tB_u} = (df_{A_t})\cdot(df_{B_u}), \quad (11)$$

where df_{A_t} = the degrees of freedom of the A_t contrast, and df_{B_u} = the degrees of freedom of the B_u contrast. Since the A_t and B_u treatment contrasts always have 1 degree of freedom each, an interaction contrast always has 1 degree of freedom.

For example, from Equation 9b, the estimate of the A_1B_1 contrast is $\widehat{A_1B_1} = (3)(.3) + (-1)(9.3) + (-1)(17.5) + (-1)(28.9) = -54.8$. From Equation 10, the sum of squares is $SS_{A_1B_1} = [(6)(-54.8)^2]/[(2)(12)] = 750.76$. The F ratio is $F_{A_1B_1} = (750.76/1)/19.15 = 39.20$. The Scheffé critical value for the 1 and 60 degrees of freedom F ratio is $S = 6F(6, 60) = 6(3.12) = 18.72$, $\alpha = .01$. Since the observed F of 39.20 is larger than 18.72, the A_1B_1 interaction contrast is judged significant. It can be concluded that the difference between the a_2 therapy group and the control group is larger under the drug conditions than under the placebo condition. In other words, the antianxiety drug increases the effectiveness of the a_2 therapy, when the effectiveness is measured by the difference between the control and therapy conditions.

Partial interactions can also be examined by starting with a B_u rather than an A_t treatment contrast. For example, earlier it was shown that the B_1 contrast [where $\mathbf{B}'_1 = (3\ -1\ -1\ -1)$] is significant. That is, on the average, the EDR is smaller under the drug conditions than under the placebo condition. It is of interest to determine whether this difference is the same for all three therapy groups. Simple Treatment B contrasts allow us to estimate the difference separately for each therapy group. A simple Treatment B contrast is denoted by $B_{u(i)}$ and defined as

$$B_{u(i)} = \sum_1^q c_j\mu_{ij}, \quad (12a)$$

where c_j = the jth coefficient in the vector $\mathbf{B}_u$. The $B_{u(i)}$ simple contrast is estimated by $\hat{B}_{u(i)}$, where

$$\hat{B}_{u(i)} = \sum_1^q c_jM_{ij} . \quad (12b)$$

For the B_1 contrast, the simple treatment contrast estimates are

$$\hat{B}_{1(1)} = 9.20,$$
$$\hat{B}_{1(2)} = 64.00,$$

and

$$\hat{B}_{1(3)} = 28.00 .$$

The sum of squares of an AB_u partial interaction can be computed from an equation analogous to Equation 6:

$$SS_{AB_u} = n\{\sum_1^p \hat{B}_{u(i)}^2 - [\sum_1^p \hat{B}_{u(i)}^2]/p\}/(\sum_1^q c_j^2) . \quad (13)$$

The degrees of freedom for an AB_u partial interaction is equal to

$$df_{AB_u} = (df_A)\cdot(df_{B_u}) . \quad (14)$$

Employing Equations 13 and 14, the sum of squares, degrees of freedom, and mean square of the AB_1 partial interaction are $SS_{AB_1} = 771.04$, $df_{AB_1} = 2$, and $MS_{AB_1} = 385.52$. The F ratio is therefore $F_{AB_1} = 385.52/19.15 = 20.13$. From Equation 8, the critical STP value is $G_2 = [6F(6, 60)]/2 = (6)(3.12)/2 = 9.36$, $\alpha = .01$. Since the observed F of 20.13 exceeds 9.36, the AB_1 partial interaction is judged significant. It is concluded that the difference between the EDR under the placebo condition and the average EDR under the three drug conditions is not the same for all therapy groups.

The precise nature of the AB_1 partial

* $p \leq .01$.

interaction can be determined by testing interaction contrasts. As in Equations 9a and 9b, an A_tB_u interaction contrast and its estimate, $\widehat{A_tB_u}$ can be defined as

$$A_tB_u = \sum_1^p c_iB_{u(i)}\,, \tag{15a}$$

and

$$\widehat{A_tB_u} = \sum_1^p c_i\hat{B}_{u(i)}\,, \tag{15b}$$

where c_i = the ith coefficient in the vector $\mathbf{A}_t$. The coefficient vector $\mathbf{A}_t$ describes the contrast among the $B_{u(i)}$ simple treatment contrasts.

An examination of the $B_{1(i)}$ simple contrast estimates suggests that the difference between the placebo and drug conditions is larger for therapy a_2 than for the control condition. The coefficient vector associated with this contrast is $A'_1 = (1\ \ -1\ \ 0)$. From Equation 15b, $\widehat{A_1B_1} = (1)(9.2) + (-1)(64.0) = -54.8$. Notice that this is the same result earlier obtained from Equation 9b. Equations 10 and 11 could be used to calculate the sum of squares and degrees of freedom for the interaction contrast. Of course, the results would again be the same. Table 3 presents an ANOVA table that summarizes all the treatment contrasts, partial interactions, and interaction contrasts tested.

Examples of partial interactions and interaction contrasts for a three-treatment design are provided by Boik (1975), who also describes alternative methods for controlling the Type I error rate when testing partial interactions and interaction contrasts.

On Getting Good Subject Mileage: Reuse of Subjects in Experiments Involving Groups

John M. Light
Department of Sociology
Princeton University

Jerald Schutte
Department of Sociology
Columbia University

This article presents a combinatorial solution to the problem of reusing subjects, which often arises in experiments on groups. Blocking and Latin square approaches are examined and contrasted. A compromise solution is offered applying a variation of "v, k, λ" balancing techniques to incomplete block designs. Suggestions are offered for testing individual effects as well as for using ordinary one-way analysis of variance.

Experimental studies involving interacting groups are an omnipresent feature of social psychological literature. In some cases, researchers are able to simulate interaction using confederates, fictitious people, computers, and the like. But many substantive areas of social psychology require that actual groups be studied, for example, group polarization (Meyers & Lamm, 1976), interaction and attraction (Insko & Wilson, 1977), bystander intervention (Wegner & Schaefer, 1978), obedience to authority (Hamilton, 1978), and certainly many others. Sometimes the group can actually be the unit from which measurements of various dependent variables are taken, for example, studies of cooperation rates in Prisoners' Dilemma games (Dawes, McTavish, & Shaklee, 1977).

One aspect of group-level experiments poses an especially difficult problem. Suppose we are going to perform a simple one-factor completely randomized experiment on a set of subjects. Five or six people per treatment may be sufficient for the discovery of any treatment effects. But suppose that instead of people, the unit of analysis is groups, for example, groups of four. Then the researcher would need five or six groups per treatment or between 20 and 24 people. It should be clear that if the experiment consists of more than a few treatment levels, or the researcher complicates the design in any way (e.g., by adding another factor), many subjects may be required.

Even assuming that enough subjects are available to carry out such a design, the researcher still must contact, schedule, and pay these additional subjects. Therefore, with all elements considered, the typical group-level experiment is logistically more difficult to carry out than an experiment in which people themselves are the unit of analysis.

This being the case, any enterprising investigator would want to determine whether there is some legitimate way to reuse subjects in group-level experiments. In this article, we consider past approaches to this problem and then present a plan that we feel is a sensible alternative.[1]

Randomized Block Designs

Techniques for the reuse of subjects have typically been based on (or related to) ran-

This article is a collaborative effort and each author contributed equally.

Requests for reprints should be sent to John M. Light, Department of Sociology, Princeton University, Princeton, New Jersey 08540.

[1] Greenwald (1976) has considered the reuse of subjects in individual-level experiments in an article that is particularly interesting for its comments on the psychological aspects of reuse. Many of his points apply to our dsicussion of group-level experiments as well, and we refer to that article when appropriate.

domized block (RB) designs. In such designs, one ordinarily assembles a number of "blocks" of size t, where t is the number of experimental treatments (or treatment combinations), and assigns one member of each block at random to each treatment (Table 1). If the assumptions of the design are met, one can calculate treatment effects as well as subject (block) effects. The linear model for the design is

$$X_{ij} = \mu + \beta_j + \tau_i + \epsilon_{ij}, \quad (1)$$

where β_j is the effect of being in the jth treatment, and τ_i is the effect of being the ith block. Since the blocks are assembled so that they are relatively homogeneous with respect to the dependent variable under study, treatment effects can be more easily discovered (though not always, since one loses degrees of freedom in attempting to incorporate block effects). Of course, blocking can be used as one aspect of more complex designs (Kirk, 1968, p. 11).

With repeated measures designs, a block may simply correspond to one experimental subject on whom more than one of the treatment levels is applied; thus the subjects are reused. In the extreme case, the researcher can administer each treatment to each subject. There is an additional bonus in this case, since subjects act as their own controls (Kirk, 1968, p. 131).

Such a repeated measures procedure is probably the ideal way to employ the RB design. On the other hand, repeated measures can only be used in the RB design if administration of one treatment does not affect the results that would be expected by administration of a later treatment. With repeated measures on nonreactive units of analysis, such as rocks or leaves (as in natural science experiments), all treatment conditions are properly independent. But if human subjects are used, such independence is unlikely.[2]

Violation of the independence assumption can occur for two reasons. First, there may be some time-order effect, that is, subjects react differently to later trials than earlier ones. For example, suppose that a researcher is studying the extent to which people are persuasive under several different motivational conditions; subjects may improve their persuasion just by practicing on earlier trials (Greenwald, 1976, p. 316). Second, there may be some interaction effects; for example, a given treatment is reacted to differently depending on the treatments preceding it.[3]

In the event that a block repeated measures design is used for groups (i.e., each block is composed of one group that is repeatedly measured on the dependent variable), both time-order and Time-Order × Treatment effects should be more pronounced, since it is well-known that groups tend to negotiate definitions of situations (Asch, 1956; Festinger, 1950; Sherif, 1936).

Note that if treatments are randomized within blocks, the main effect of time order cancels out in treatment comparisons. It does, however, contribute to the error term and therefore reduces the power of the design. From this perspective, a repeated measure group-level RB design will tend to be conservative, though relatively inefficient (we reject fewer null hypotheses than we

Table 1
Randomized Block Design

Block	Treatment 1	2	3	4	5
1	0_1	0_2	0_3	0_4	0_5
2	0_1	0_2	0_3	0_4	0_5
3	0_1	0_2	0_3	0_4	0_5
4	0_1	0_2	0_3	0_4	0_5

Note. Each 0 represents one observation on a member of that block.

[2] Actually, the statistical requirement for an unbiased F test in a repeated measures design is that the Treatment × Treatment covariance matrix have equal off-diagonal elements (Winer, 1971, p. 277). This condition is satisfied if treatment covariances are only a result of measurements for each pair of treatments containing members of the same blocks (cf. Kirk, 1968, p. 140).

[3] All three types of context effects discussed by Greenwald (1976) are basically Time × Treatment interaction. His discussion of such effects is more detailed and contains more examples than ours. Much of that discussion applies to cases in which entire groups are reused as well.

Table 2
Latin Square Design

Subject	Time order 1	2	3	4
1	A	B	C	D
2	B	C	D	A
3	C	D	A	B
4	D	A	B	C

Note. Each letter represents a different treatment.

should). Time × Treatment interaction can similarly be removed by more elaborate randomization. But other interactions cannot and may either further obscure actual results or create spurious ones.

Latin Square Designs

One way to increase the power of an RB repeated measures design and to deal with the main effects of time order is to have each subject take the treatments in different time orders. In this way, each treatment is given first during one round, second during another, third during another, and so on. This should allow the researcher to extract these time-order effects from the error term, thereby increasing the power of the test.

In fact, this is just the approach taken in a Latin square (LS) design (Table 2). For a repeated measures LS design, we interpret the rows of the square as observational units (people, groups, etc.), the columns as the different times, and the table entries as treatments. The treatments are assigned so that each treatment appears only once in each row and column. In this way, each subject takes each treatment only once, and each treatment is taken at each possible different time only once. This is precisely the balancing condition previously described as desirable. The linear model for the LS design is

$$X_{ijkm} = \mu + \alpha_i + \beta_j + \gamma_k + \epsilon_{m(ijk)}, \quad (2)$$

where μ is the grand mean, α_i is the effect of row i (subject), β_j is the effect of column j (time), γ_k is the effect of treatment k, and ϵ is the experimental error.

At first, one might think that this design solves our problems. Certainly the major problem of controlling for time-order effects has been taken care of. At least a treatment effect is not suppressed by including the main effect of time order in the error term.

However, this design does not deal with interaction effects. It must be assumed that there are no interactions between time and treatment, time and subject, or treatment and subject (nor can there be any three-way interaction). If any exist, they will be confounded with treatment effects (in the case of Time × Subject interaction) or experimental error (in the case of Time × Treatment or Treatment × Subject).[4] Since the error term appears in the denominator of the F statistic for all main effects, occurrence of these last two types of interaction produces a conservative test (Cochran & Cox, 1957). On the other hand, if there is reason to believe that such interaction effects will be present, this conservative aspect of the LS design may be inefficient—a strong treatment effect is the only sort that would be detected.

Although Time × Subject interaction is confounded with treatment effects, if one is dealing with groups as the unit of analysis, it is probable that this type of interaction will not be a problem. In the case of Time × Group interaction, we are postulating that groups learn differently: Time order has different effects on different groups. This is an unlikely possibility. Moreover, it does not seem likely that groups will have peculiar responses to particular treatments. Thus Treatment × Group interaction should be an unlikely problem as well.

Both of these generalizations are based on the fact that groups tend to be more homogeneous than a comparable number of single individuals, since averaging of many individ-

[4] Evidently many people believe that all of these interactions will be confounded with main treatment effects, but this is not so. Interactions involving treatment (Time × Treatment or Subject × Treatment) will increase variance about the treatment mean, thus adding to error and obscuring real treatment effects. Only Time × Subject interaction will create between-means variance that artificially increases apparent treatment effects.

ual properties is possible. The larger the group, the more likely this is to be true. Although there are experiments in which the characteristics of particular individuals in each group may be important (e.g., problem solving, in which individual insight is the key to the solution), many if not most group experiments can rely on this homogenizing effect to create relatively similar-acting groups.

But Time × Treatment interaction (Greenwald, 1976) does pose a problem, much as it does with RB repeated measures designs. To say that such interaction exists is to say that a treatment has a different effect at a particular time. For example, it may be that in a bargaining game, large payoffs have more impact when administered in an early or late session; in the first case, there might be a primacy effect, and in the second, subjects would have had a chance to develop enough perspective to realize the magnitude of the payoff. As argued earlier, this could well be a problem when repeated measure is taken on individuals; it will be even worse when groups are the unit measured. The reason this is such a problem for group repeated measures designs, whether RB or LS, again rests on the fact that groups tend to be a source of reality conformation. This being the case, we would expect that group members' orientations toward a given treatment would be solidified in the group context, the more often that group context is reused. This would tend to exaggerate the Time × Treatment interaction. An individual alone would perhaps be less willing to make such judgments.

Besides being weakened by the presence of this interaction effect (an effect that we have argued will often be present), LS designs, whether applied to individuals or groups, suffer from another, even more basic, problem. Kirk (1968, p. 158) notes that it is impractical to use LS designs of dimension less than 5 × 5 with only one observation per cell (as in Table 2), since there are not enough degrees of freedom to give the design any power. This gives the researcher two choices: to replicate the square (thereby doubling the number of experimental units and to some extent defeating the purpose of the repeated measures procedure) or to use a fairly large square. But if the latter course can be followed (i.e., the experimenter is able to vary the number of treatment levels), fatigue effects can still ruin the experiment. Obviously, subjects' interest in the treatments will wane as they take more and more treatments. This may produce motivation to find a single mode of responding to all treatments, a strategy that would be exacerbated in the group context. As a result, if groups are given many treatments (as in a sizable LS design), later treatments will often produce homogeneous responses and are hence uninformative. In many cases, it is doubtful that the added degrees of freedom gained in the larger LS could make up for this increased homogeneity of response, and the treatment effects could again be lost.

A New Method for Reusing Subjects

We have argued that for logistic reasons of recruiting and scheduling as well as for statistical reasons of intersubject variability, the reuse of subjects is especially beneficial. But we have also noted that the typically used RB and LS repeated measures designs are likely to be unsatisfactory. The more similar each treatment situation is to previous and succeeding ones, the more the responses will tend to be interdependent. Moreover, we have argued that these dependencies should be even stronger with groups, since the group context offers members the opportunity to create some type of joint perspective as to the proper mode of orientation and behavior.

Therefore, we would like to propose a different statistical approach, which takes advantage of the fact that groups are the unit of analysis. Since reuse of the same group in repeated measures designs often creates the problem of interaction effects, we suggest a format that will systematically rotate people through different groups but that will do so in such a way that no two people will ever be in the same group more than once. In other words, we will arrange to guarantee that on each trial, a subject will receive the experimental treatment with

an entirely new and uniquely constituted group.

We thus make use of the fact that a large part of the context for each experimental treatment is a subject's group. By reusing subjects but not groups, we make certain that this important context is entirely novel on each trial. Under these conditions, it is likely that subjects will treat the trials as largely independent. Although statistically, individuals are still subject to sequence or carry-over effects, reconstituting the unit of analysis (i.e., the groups) each time assures that we minimize the problem of intertrial dependencies, particularly Time-Order × Treatment interaction.

The format for our approach stems from Yates (1936), who developed a class of designs that he saw as one solution to the restrictions inherent in randomized block designs (i.e., that one must have the same number of subjects per block as number of treatments). In such designs, each block is repeatedly measured but on fewer than all treatment levels. Yates called this procedure an "incomplete block" design to indicate that members of the block are given an incomplete subset of treatment levels of the independent variable.

This class of designs can be described as a combinatorial problem: How many ways can some $k < t$ treatment levels be assigned to blocks (individuals in a repeated measures design), and how many blocks will suffice. The binomial coefficient (t choose k) specifies the number of blocks (b) needed if all possible selections of k from t treatments are constructed, with the proviso that each treatment level is replicated r times and that any two treatments are paired together in a given block λ times.

Combinatorial problems with these constraints are often used in conjunction with creating balanced incomplete block (BIB) designs, such that the number of treatments remains constant across blocks. These designs, called (t, k, b, r, λ) configurations, are formally defined as a family of b subsets of a set S consisting of t elements, such that for some fixed k and λ, each subset has k elements, and each pair of elements of S occurs together exactly λ times. Given these assumptions, the following equations must hold (Fisher, 1940):[5]

$$N = rt = bk \tag{3}$$

$$r(k-1) = \lambda(t-1). \tag{4}$$

For example, consider the set of seven elements to be S = {1, 2, 3, 4, 5, 6, 7}. Now suppose we specify the following subsets of the power set of S: {1, 2, 4}, {2, 3, 5}, {3, 4, 6}, {4, 5, 7}, {5, 6, 1}, {6, 7, 2}, {7, 1, 3}. Here $b = 7$, $t = 7$, $k = 3$, and $\lambda = 1$; any two numbers appear in the same subset only once.

The matrix summarizing these sets is called an incidence matrix. In our example, the incidence matrix is

1101000
0110100
0011010
0001101
1000110
0100011
1010001

The number of rows is equal to the number of subsets b, and the number of columns is equal to the number of elements t. The number of entries in the columns is k. The number of entries in the rows is r.

In the language of experimental designs that use incomplete blocks, we have the following equivalences: t = treatment levels in the experiment[6] (the number of columns);

[5] This is easily proven. Since k and λ are fixed, and t is constant for any given experiment, r must be the same for each treatment. Hence, there are rt appearances of the treatments altogether. But there are b blocks, each of which receives k treatments. This must also equal the total number of appearances. Thus $bk = rt = N$. Further, since any one treatment level may appear exactly λ times with any other of the remaining $(t-1)$ treatment levels, it follows that the total number of times a treatment pair containing any one treatment will occur is $\lambda(t-1)$. But there are $(k-1)$ other treatment levels in any treatment's subset that appear in exactly r replications. This also equals the total number of times a treatment pair will occur. Hence, $r(k-1) = \lambda(t-1)$.

[6] A notational problem arises here. Originally, these problems were called "v, k, λ" designs; but more

b = the number of blocks (the number of rows); k = the number of treatment levels assigned to blocks (the number of 1s in each row); r = the number of replications of each treatment level (the number of 1s in each column); λ = the number of times any two treatment levels appear together in a block. For a design to be balanced, Equations 3 and 4 must hold, and t, b, k, r, and λ are integers. That this is true implies that k must be less than t, that is, each block must necessarily be assigned less than all of the treatments. It is this requirement that defines the block design as incomplete.

We now deal with a subset of the balanced incomplete block designs and demonstrate this subset's utility in group experiments (Table 3). The subset can be described with the following constraints. First, only those designs in which $\lambda = 1$ are dealt with. This consists of the subset of designs in which each treatment appears with any other treatment only once. Second, the designs are further restricted by assuming that these blocks are individuals, such that we essentially have an incomplete repeated measures procedure. Note that each column (Table 3) contains the same number of people and that each pair of people appears in the same column only once in the experiment. If we interpret the columns as being groups in addition to being treatments, then certainly for the example in Table 3, groups are being uniquely reconstituted each time, in accordance with our earlier desiderata. The following simple proposition shows that this will always be true when $\lambda = 1$ and (within the context of v, k, λ designs) will be true in only that case. It can be thought of as evidence for a type of "duality"; in this class of BIB designs, limiting the number of times that treatments appear together in the same block also restricts the number of times that people appear together.

recently, t has been used instead of v to denote the number of treatment levels. So we have used the term "v, k, λ" to refer to the class of problems, but we use t instead of v to denote the number of treatments, since most books on experimental design use such notation.

Table 3
Balanced Incomplete Block Design

	Treatment		
Block	1	2	3
1	0_1		0_2
2		0_1	0_2
3	0_1	0_2	

Note. Each 0 is one observation from the row block.

Proposition

In a v, k, λ configuration, $\lambda = 1$ if and only if no two people appear together in the same group more than once.

Proof. Let i and j be integers 1 thru t inclusive, let L and m be integers 1 thru b inclusive, and let $\mathbf{A}$ be the incidence matrix. Assume $\lambda = 1$, and suppose that two people appear together more than once. This implies that $\mathbf{A}_{Li} = \mathbf{A}_{mj} = 1$ for some pair of subjects L and m and some treatments i and j. But $\lambda = 1$ implies that $\mathbf{A}_{Li} = \mathbf{A}_{Lj} = 1$ for one and only one L, a contradiction. Now assume that no two people appear together more than once, and assume $\lambda = n > 1$. This means that n integers L_p exist, such that for $i = j$, $\mathbf{A}_{L_pi} = \mathbf{A}_{L_pj} = 1$ for all n values of L. But this means that two people, for example L_1 and L_2, see each other at least twice, in treatments i and j, a contradiction. This completes the proof.

It is interesting that by restricting our attention to v, k, λ designs in which $\lambda = 1$, we can ensure the added advantage that (to use our interpretation) no pair of subjects meets more than once in the course of the experiment. In this way, uniqueness of each experimental situation can be guaranteed, thereby discouraging subjects from treating later treatments like previous ones. We call this class of designs group balanced incomplete block (Group BIB) designs.

In addition to the formal consideration shown in the proposition, there are several practical considerations that we find limit the researcher's choice of group BIB designs. First, if we were to let λ be other than 1, then people could meet more than once during the course of the experiment. Although this might be acceptable in some types of

Table 4
Several Group Balanced Incomplete Block Designs

Design parameters				
t	r	b	k	λ
3	2	3	2	1
4	3	6	2	1
5	4	10	2	1
6	5	15	2	1

Note. Each row represents one design.

experiments, clearly our desire to make each experimental group maximally different causes us to prefer uniquely constituted groups. Hence, for this study, we restrict our attention to designs in which $\lambda = 1$. Second, observe that k must be at least 2, since otherwise subjects are not reused. But since $\lambda = 1$, if k is larger than 2, an inordinately large number of treatments are required to create a group BIB design (7 at a minimum and 13 or higher after that; see Table 11.3, Cochran & Cox, 1957, p. 469). Further restricting our attention, then, to cases in which $k = 2$, it follows from Equations 3 and 4 that $r = t - 1$; that is, the size of the group will be one less than the number of treatments.

Besides the practical benefit of keeping k set at 2, there is a possible substantive benefit: We are assured that any individual will receive the minimum possible number of treatments (while still being reused), thus minimizing the possibility of fatigue and/or learning effects. This is discussed more extensively later.

Since λ and k are restricted to be constants by these considerations, it follows again from Equations 1 and 2 that for practical purposes (i.e., for values of t at or below 7), the entire design is specified by one parameter t. If a researcher knows the number of treatment levels to be given, both the group size r and the number of subjects needed b can be determined. Table 4 enumerates some of these designs.

Advantages of the Design

Such subsets of incomplete block designs are important for several reasons. First, it can be observed that the number of subjects needed to produce one group observation in each treatment (i.e., b) will be considerably less than the minimum number of subjects needed for a RB or LS design, even when this incomplete design is reconstituted more than once to achieve multiple observations per treatment level.

Second, if the group measure is taken on the individual and aggregated, our design allows a row effect (i.e., subject effect) to be computed and used to adjust the treatment mean as in any incomplete block design. That is,

$$X_{ij} = \mu + \beta_i + \tau_j + \epsilon_{ij}, \qquad (5)$$

where the estimate of β_i is used to adjust the estimate of τ_j. This means we can account for the effects of an individual being involved in a repeated measure and use this information to help assess the treatment effects.

More importantly, however, when the measure is at the group level, this procedure minimizes the problem inherent in assuming intertrial independence. Since subjects take more than one treatment, such independence will not hold in general. However, as previous arguments suggest, the group BIB design is explicitly arranged to minimize violation of this assumption under a usefully wide set of circumstances. Thus we think of the statistical analysis of a group BIB design as reducing to a one-way analysis of variance (ANOVA) in which each level of the treatment variable has one (group) observation. Each such design, conducted with new subjects, constitutes an additional observation per treatment level. Use of an ordinary one-way ANOVA on such data is justified because each group (i.e., unit of analysis) is independent and uniquely constituted, and each individual appears in the minimum possible repetitions (2).

As we suggested earlier, the fact that subjects have not seen each other before should create novel contexts that discourage use of information from previous trials. Further, no subject will ever have more than one such previous trial. Naturally, in experiments in which learning is an important variable (e.g.,

in studies of group problem solving in which problems are similar and in which time might be the dependent variable), we would not expect this kind of argument to hold. Generally, when the treatments are more the focus than the group context, there are likely to be carry-over effects. If the group context is the focal point for the subjects, however (with treatments more in the background, such as conditions for negotiations, etc.), we would expect group interaction to be less affected, and the approach presented here may be helpful.

These advantages provide intuitive and partial statistical grounds for assuming that such observations are independent. This eliminates much of the need to worry about time-order and various interaction effects, as in RB and LS designs.

Conclusion

We have discussed the disadvantages of doing group-type experiments by the usual methods—completely randomized factorial designs—as compared with attempting to reuse subjects in randomized block repeated measures or Latin square designs with time order as one of the nuisance variables. We believe our approach offers a good compromise between these techniques. By allowing subjects to be reused only in certain restricted ways, we have created conditions in which the usual problems of repeated measures designs should be minimized. At the same time, the researcher avoids the (often prohibitive) costs associated with recruiting and scheduling enough subjects to fill a completely randomized design.

The solution we have suggested is a modest one. On the other hand, it is important to see that its weaknesses differ from the weaknesses of other kinds of repeated measures designs; thus the group balanced incomplete block design should be thought of as another tool in the researcher's toolbag, one which will be useful only some of the time. We believe that when it is applicable, though, it may simplify experimental procedures significantly, enough to warrant being considered for use in any experiments on groups.

Comparison of Sequences

Lawrence J. Hubert
School of Education, University of California, Santa Barbara

The problem of comparing K numerical sequences, each defined over the same n objects, is approached through the use of a K-variate scoring function. Besides encompassing some old work of Spearman, the sequence-comparison paradigm can be used to discuss a number of separate data-analysis procedures of particular interest to the behavioral sciences, for example, nominal scale response agreement among multiple raters, Friedman's test, Kendall's coefficient of concordance, Page's test, and so on. The major intent of this article is pedagogical, and it emphasizes a general conceptual framework that conveniently organizes a number of well-known statistical strategies.

It should be apparent to every beginning student of statistics that many, if not most, data-analysis strategies are based on sums of squared differences. As is well-known, sums of this type appear in the definition of a variance, in least-squares regression, in chi-square goodness-of-fit tests, and so on. Upon reflection, however, a psychologist with even a superficial knowledge of test theory might consider this reliance on squared differences misplaced. As Spearman (1906) noted some 70 years ago, extreme scores are expected to contain relatively large amounts of measurement error; consequently, statistical procedures that accentuate these extremes by an additional process of squaring could easily compound the difficulties inherent in making inferences from fallible data. This last observation, along with some outdated problems of computational tractability, originally lead Spearman to consider an alternative measure of correlation, now called Spearman's footrule, based on a sum of absolute differences between two numerical sequences. In fact, Spearman proposed the footrule as a direct competitor to his more well-known rank correlation coefficient based on an analogous sum of squared differences.

Partial support of this research was supplied by National Science Foundation Grant SOC-77-28227.

Requests for reprints should be sent to Lawrence J. Hubert, Graduate School of Education, University of California, Santa Barbara, California 93106.

Although Spearman's contributions are now important primarily for historical reasons, this early work still represents a significant effort to develop alternative norms for the comparison of two numerical sequences. In particular, the present discussion is concerned with the more general problem of measuring the correspondence among K numerical sequences using an arbitrary scoring function, but I rely on the two simple norms presented by Spearman as an introductory example. Besides suggesting several interesting theoretical generalizations of Spearman's ideas, these extensions to multiple sequences lead to several new insights into the superficially different problem of measuring nominal scale response agreement among multiple raters (cf. Cohen, 1968; Fleiss, Cohen, & Everitt, 1969; Hubert, 1977). In addition, the same general structure is relevant to the problem of analyzing m rankings, for example, Friedman's two-way analysis of variance by ranks (Friedman, 1937), Kendall's coefficient of concordance (Kendall, 1970), and Page's L test (Page, 1963). It should be noted at the outset that this article's major contribution is pedagogical, and I do not intend to advocate any new data-analysis procedures. Inasmuch as all of the techniques mentioned here have been discussed in detail in the literature, there is no need to review the specifics of these individual data-analysis strategies. Apparently, the ubiquitous nature of the sequence-comparison problem has not been recognized in the methodological litera-

ture of psychology, and for this reason alone, an explicit discussion of the general paradigm may be of value to develop in greater depth.

Background

To introduce some terminology, suppose that $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$ denote two numerical sequences in which the corresponding elements x_i and y_i are matched in some manner. Clearly, this framework is the natural context for developing a measure of association based on the n bivariate pairs $(x_1, y_1), \ldots, (x_n, y_n)$. When rank correlations are desired, an initial transformation of the xs and the ys to ranks may also be imposed, but for our purposes this reduction is unnecessary. At least for now, the original sequences of the xs and the ys can be retained.

Instead of proceeding directly to calculate a traditional Pearson product-moment correlation coefficient, suppose that a more general measure of proximity between the two sequences is of initial interest. In particular, let $f(\cdot, \cdot)$ be a bivariate function and define a summary measure of proximity between the sequences $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$ by the index Γ:

$$\Gamma = \sum_{i=1}^{n} f(x_i, y_i).$$

Although the function $f(\cdot, \cdot)$ is arbitrary, two special cases are of obvious importance. If $f(x, y) = |x - y|$, then Γ forms the basis for Spearman's footrule; if $f(x, y) = (x - y)^2$, the basis for Spearman's more common rank correlation statistic is obtained. As a convention, Γ_α will refer to an index defined by $f(x, y) = |x - y|^\alpha$; thus, the footrule corresponds to the use of Γ_1 and Spearman's more common statistic corresponds to the use of Γ_2.

Although various normalizations of Γ may be desirable to transform a raw index into a suitably restricted measure of association, examination of these normalizations can be delayed until later and then discussed in greater generality. As it stands, the raw index Γ is sufficient for purposes of hypothesis testing in the permutation context; for example, the tables given in Kendall (1970) for the better known Spearman index of rank correlation are given in terms of Γ_2. To carry out such a test, an index of the form specified by Γ is evaluated under the notion of *independence*, in which all permutations of the ys against the fixed sequence of xs are considered equally likely (or equivalently, fixing the xs and permuting the ys). Thus, the exact null distribution of Γ can be obtained by evaluating the index over all $n!$ permutations of the ys and tabulating the resulting frequency distribution. If the index Γ is sufficiently extreme when compared to this distribution, the hypothesis of independence can be rejected.

Unless the xs and the ys are untied within their respective sets and a transformation to ranks (or to some other canonical form) is imposed, the permutation distribution has to be recalculated for each different application. Since this is a very extensive computational burden, large-sample (normal) approximations are desirable. As it turns out, these approximations are fairly easy to obtain through general formulas for the mean and variance of Γ, which can then be specialized for particular defining functions $f(\cdot, \cdot)$.

Γ as a Bilinear Permutation Statistic

The index Γ has the form of a bilinear permutation statistic (see Puri & Sen, 1971), and thus, assuming all permutations of the ys are equally likely,

$$E(\Gamma) = (1/n) \sum_{j=1}^{n} \sum_{i=1}^{n} f(x_i, y_j);$$

$$\operatorname{var}(\Gamma) = \{1/[n(n-1)]\}[(1/n)A_1 - (A_2 + A_3) + nA_4],$$

where

$$A_1 = [\sum_{j=1}^{n} \sum_{i=1}^{n} f(x_i, y_j)]^2;$$

$$A_2 = \sum_{j=1}^{n} [\sum_{i=1}^{n} f(x_i, y_j)]^2;$$

$$A_3 = \sum_{i=1}^{n} [\sum_{j=1}^{n} f(x_i, y_j)]^2;$$

$$A_4 = \sum_{j=1}^{n} \sum_{i=1}^{n} f(x_i, y_j)^2.$$

Specializing these formulae for the case in which the sequences $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$

represent the untied ranks of 1, 2, ..., n in some order, we have

Γ_1:

$$E(\Gamma_1) = (n^2 - 1)/3;$$
$$\mathrm{var}\,(\Gamma_1) = (n + 1)(2n^2 + 7)/45,$$

Γ_2:

$$E(\Gamma_2) = n(n^2 - 1)/6;$$
$$\mathrm{var}\,(\Gamma_2) = [1/(n - 1)][(n^3 - n)/6]^2.$$

The mean and variance of Γ_1 for untied ranks are available in Spearman (1906) and those for Γ_2 in Kendall (1970). Finally, under very mild conditions on the values assigned by the function $f(\cdot, \cdot)$, Γ can be shown asymptotically normal as $n \to \infty$. For a discussion of several possible sufficient conditions, the reader is referred to Puri and Sen (1971, p. 72) and Hoeffding (1951).

Correlations Among Indices

In addition to information regarding the single index Γ that can be obtained as shown above, it is relatively straightforward to calculate the correlation between two such indices, say Γ and Γ', based on two different bivariate functions $f(\cdot, \cdot)$ and $f'(\cdot, \cdot)$. First, the sum of $f(\cdot, \cdot)$ and $f'(\cdot, \cdot)$ is considered as a new bivariate function, and the variance of this index is obtained. The covariance for Γ and Γ' is then isolated by subtracting off the variances for Γ and Γ' and dividing by 2. Carrying out this process leads to the following general expression for the covariance between Γ and Γ' over the same $n!$ permutations:

$$\mathrm{cov}\,(\Gamma, \Gamma') = \{1/[n(n - 1)]\}[(1/n)B_1 - (B_2 + B_3) + nB_4],$$

where

$$B_1 = [\sum_{j=1}^{n}\sum_{i=1}^{n} f(x_i, y_j)][\sum_{j=1}^{n}\sum_{i=1}^{n} f'(x_i, y_i)];$$

$$B_2 = \sum_{j}[\sum_{i} f(x_i, y_j)\sum_{i} f'(x_i, y_j)];$$

$$B_3 = \sum_{i}[\sum_{j} f(x_i, y_j)\sum_{j} f'(x_i, y_j)];$$

$$B_4 = \sum_{j=1}^{n}\sum_{i=1}^{n} f(x_i, y_j)f'(x_i, y_j).$$

Finally, normalizing by the square root of the variances for Γ and Γ', the Pearson correlation between Γ and Γ' can be derived. As an example for the special case of $\Gamma \equiv \Gamma_1$ and $\Gamma' \equiv \Gamma_2$ and where untied ranks are used for the xs and ys, this procedure leads to the following simplification:

$$\rho(\Gamma_1, \Gamma_2) = \frac{3}{\sqrt{10}}\left(\frac{n^2 + 1}{\sqrt{(n^2 - 1)(n^2 + \frac{7}{2})}}\right).$$

Surprisingly, this correlation is bounded away from 1 for large n and approaches $3/\sqrt{10}$ as $n \to \infty$. This situation contrasts with an asymptotic correlation of 1.00 between Spearman's rank correlation index based on Γ_2 and Kendall's tau statistic (Kendall, 1970).

Although the details of index correlation will not be developed in any further detail, it is significant to note that such correlations are easily obtained once the variance of a general statistic, such as Γ, is derived (or the later extensions of Γ to multiple sequences). Thus, when a researcher is faced with alternative choices for an index, it may be of practical interest to know how highly the various choices intercorrelate under independence and for various values of n or, more specifically, to know if the intercorrelations are less than unity even when n is assumed infinite.

Other Applications of Γ

Besides the Spearman indices, the measure Γ also includes several other statistics of interest to psychology that have been developed in comparative isolation. For instance, as discussed by Hubert (1978), the index Γ can be used to develop Cohen's (1968) index of nominal scale response agreement between two raters. Here, the numerical sequence x_1, x_2, ..., x_n represents the labels for the R categories used by Rater 1 to classify n objects, and y_1, y_2, ..., y_n represents the labels used by Rater 2 to classify the same n objects into C categories. Typically, $R = C$ and the number of objects placed in the same category by the two raters is of interest. More generally, we can define

$$f(x_i, y_j) = w_{uv},$$

if x_i is placed in the category labeled u by Rater 1, $1 \leq u \leq R$, and in the category labeled v by Rater 2, $1 \leq v \leq C$. The index Γ

is then a raw index of weighted nominal scale response agreement that can be subjected to various normalizations to provide an appropriately restricted final index. As with the Spearman statistics, however, the raw index Γ can be considered by itself for the purposes of hypothesis testing. It should be apparent that an appropriate choice of weights (e.g., $w_{uv} = |u - v|^{\alpha}$) leads us directly back to the index Γ_α. Also, for Cohen's problem of nominal scale response agreement, the effect of different choices for the weights can be partially assessed by the general covariance formula between Γ and Γ' given earlier.

Multiple Sequences

The obvious extension of the index Γ to three sequences $x_1, \ldots, x_n$; $y_1, \ldots, y_n$; $z_1, \ldots, z_n$ relies on a trivariate function $g(x_i, y_j, z_k)$. As a notation, suppose the index associated with this function is given by Λ_3:

$$\Lambda_3 = \sum_i g(x_i, y_i, z_i), \tag{1}$$

and assume that all $n!$ reorderings of the ys and all $n!$ reorderings of the zs are equally likely under a hypothesis of independence. By carrying out the usual moment calculations (cf. Hubert, 1979),

$$E(\Lambda_3) = \frac{1}{n^2}\Big[\sum_{i,j,k} g(x_i, y_j, z_k)\Big];$$

$$\begin{aligned} V(\Lambda_3) = {} & \frac{2n-1}{n^4(n-1)^2}\Big[\sum_{i,j,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \frac{n-2}{n(n-1)^2}\sum_{i,j,k} g(x_i, y_j, z_k)^2 \\ & - \frac{1}{n^2(n-1)^2}\Big\{\sum_i\Big[\sum_{j,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_j\Big[\sum_{i,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_k\Big[\sum_{i,j} g(x_i, y_j, z_k)\Big]^2\Big\} \\ & + \frac{1}{n^2(n-1)^2}\Big\{\sum_{i,j}\Big[\sum_k g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_{i,k}\Big[\sum_j g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_{j,k}\Big[\sum_i g(x_i, y_j, z_k)\Big]^2\Big\} \\ \approx {} & \frac{2}{n^5}\Big[\sum_{i,j,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \frac{1}{n^2}\sum_{i,j,k} g(x_i, y_j, z_k)^2 \\ & - \frac{1}{n^4}\Big\{\sum_i\Big[\sum_{j,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_j\Big[\sum_{i,k} g(x_i, y_j, z_k)\Big]^2 \\ & + \sum_k\Big[\sum_{i,j} g(x_i, y_j, z_k)\Big]^2\Big\} \\ & + \text{lower order terms.} \end{aligned} \tag{2}$$

The general form for these moment expressions for K sequences follow in a similar manner. If $x_1^{(r)}, \ldots, x_n^{(r)}$, for $1 \le r \le K$, denote the K sequences, and if the index Λ_K is defined using a K-variate function $h[x_{i_1}^{(1)}, x_{i_2}^{(2)}, \ldots, x_{i_K}^{(K)}]$, then

$$\Lambda_K = \sum_i h[x_i^{(1)}, x_i^{(2)}, \cdots, x_i^{(K)}];$$

$$E(\Lambda_K) = \frac{1}{n^{K-1}}\sum_{i_1,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}];$$

$$\begin{aligned} \operatorname{var}(\Lambda_K) = {} & -\left\{\frac{1}{n^{K-1}}\sum_{i_1,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\right\}^2 \\ & + \frac{1}{n^{K-1}}\sum_{i_1,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]^2 \\ & + \left[\frac{1}{n(n-1)}\right]^{K-1} \\ & \times\Big(\Big\{\sum_{i_1,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(k)}]\Big\}^2 \\ & - \sum_{i_1}\Big\{\sum_{i_2,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\Big\}^2 \\ & - \cdots - \sum_{i_K}\Big\{\sum_{i_1,\cdots,i_{K-1}} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\Big\}^2 \\ & + \sum_{i_1,i_2}\Big\{\sum_{i_3,\cdots,i_K} h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\Big\}^2 \\ & + \cdots + \sum_{i_{K-1},i_K}\Big\{\sum_{i_1,\cdots,i_{K-2}} \\ & h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\Big\}^2 \\ & - \cdots - \cdots (-1)^K \\ & \times \sum_{i_1,\cdots,i_K}\{h[x_{i_1}^{(1)}, \ldots, x_{i_K}^{(K)}]\}^2\Big) \end{aligned}$$

$$\approx\left(\frac{K-1}{n^{2K-1}}\right)\{\sum_{i_1,\cdots,i_K} h[x_{i_1}{}^{(1)},\ldots,x_{i_K}{}^{(K)}]\}^2 + \frac{1}{n^{K-1}}\{\sum_{i_1,\cdots,i_K} h[x_{i_1}{}^{(1)},\ldots,x_{i_K}{}^{(K)}]\}^2 - \frac{1}{n^{2(K-1)}}(\sum_{i_1}\{\sum_{i_2,\cdots,i_K} h[x_{i_1}{}^{(1)},\ldots,x_{i_K}{}^{(K)}]\}^2 + \cdots + \sum_{i_K}\{\sum_{i_1,\cdots,i_{K-1}} h[x_{i_1}{}^{(1)},\ldots,x_{i_K}{}^{(K)}]\}^2) + \text{lower order terms.}$$

Contingency Table Applications

As one particular application of the index Λ_k, suppose a threefold contingency table is given having R rows, S columns, and T layers, and let n_{rst} denote the number of observations in row r, column s, and layer t. If w_{rst} defines a fixed weight attached to the corresponding cell, then the raw index Λ_3 can be written as

$$\Lambda_3 = \sum_{r,s,t} w_{rst} n_{rst},$$

where the function $g(x_i, y_j, z_k)$ in Equation 1 is defined as w_{rst} if x_i belongs to row r, y_j belongs to column s, and z_k belongs to layer t. The moment formulas reduce in a similar manner; for instance,

$$E(\Lambda_3) = \frac{1}{n^2}\sum_{r,s,t} w_{rst} n_{r\cdot\cdot} n_{\cdot s\cdot} n_{\cdot\cdot t};$$

and using the approximate variance that ignores lower order terms,

$$\text{var}(\Lambda_3) \approx \frac{2}{n^5}(\sum_{r,s,t} w_{rst} n_{r\cdot\cdot} n_{\cdot s\cdot} n_{\cdot\cdot t})^2 + \frac{1}{n^2}(\sum_{r,s,t} w^2_{rst} n_{r\cdot\cdot} n_{\cdot s\cdot} n_{\cdot\cdot t}) - \frac{1}{n^4}[\sum_r n_{r\cdot\cdot}(\sum_{s,t} w_{rst} n_{\cdot s\cdot} n_{\cdot\cdot t})^2 + \sum_s n_{\cdot s\cdot}(\sum_{r,t} w_{rst} n_{r\cdot\cdot} n_{\cdot\cdot t})^2 + \sum_t n_{\cdot\cdot t}(\sum_{r,s} w_{rst} n_{r\cdot\cdot} n_{\cdot s\cdot})^2].$$

If we let $p_{r\cdot\cdot} = n_{r\cdot\cdot}/n$, $p_{\cdot s\cdot} = n_{\cdot s\cdot}/n$, and $p_{\cdot\cdot t} = n_{\cdot\cdot t}/n$, then

$$E(\Lambda_3) = n\sum_{r,s,t} w_{rst} p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t};$$

and

$$\text{var}(\Lambda_3) \approx n[2(\sum_{r,s,t} w_{rst} p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t})^2 + \sum_{r,s,t} w^2_{rst} p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t} - \sum_r p_{r\cdot\cdot}(\sum_{s,t} w_{rst} p_{\cdot s\cdot} p_{\cdot\cdot t})^2 - \sum_s p_{\cdot s\cdot}(\sum_{r,t} w_{rst} p_{r\cdot\cdot} p_{\cdot\cdot t})^2 - \sum_t p_{\cdot\cdot t}(\sum_{r,s} w_{rst} p_{r\cdot\cdot} p_{\cdot s\cdot})^2].$$

When $R = S = T$, and three raters are assumed to define the dimensions of the three-way contingency table, a number of raw indices of rater agreement can be obtained by varying the definition of w_{rst}. As indicated by David and Barton (1962) and developed in the rater context by Hubert (1977), many different concepts of agreement are possible. I shall list several of these definitions later but give the specializations of the moments for only the first three since these appear to be the most natural.[1] The reader is referred to David and Barton (1962) for a discussion of asymptotic normality for these various alternatives when the weights are restricted to be dichotomous (i.e., $0 - 1$) or when they arise as sums of dichotomous weights.

1. DeMoivre: An agreement occurs if and only if all raters place an object in the same category. Thus, letting $w_{rst} = 1$ if $r = s = t$ and 0 otherwise, we obtain

$$E(\Lambda_3) = n\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot} p_{\cdot\cdot r};$$

$$\text{var}(\Lambda_3) \approx n[2(\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot} p_{\cdot\cdot r})^2 + \sum_r p_{r\cdot\cdot} p_{\cdot r\cdot} p_{\cdot\cdot r}(1 - p_{\cdot r\cdot} p_{\cdot\cdot r} - p_{r\cdot\cdot} p_{\cdot\cdot r} - p_{r\cdot\cdot} p_{\cdot r\cdot})].$$

Alternatively, if we let a_{rs} denote a weighting between Raters 1 and 2, b_{rt} a weighting

[1] It should be noted that these expressions correspond to those given in Hubert (1977) except for a typographical error in the first definition due to DeMoivre. Here, the sums over k should have been products over k; also, the last such product should be over $k' \neq k$ (this last change also points out a misprint in David and Barton, 1962). The correct formulas are given in the text of the present article.

between Raters 2 and 3, and c_{st} a weighting between Raters 1 and 3, w_{rst} = minimum (a_{rs}, b_{rt}, c_{st}). In the specific cases we are considering here, $a_{rs} = 1$ if $r = s$ and 0 otherwise, $b_{rt} = 1$ if $r = t$ and 0 otherwise, and $c_{st} = 1$ if $s = t$ and 0 otherwise. This notation will be used below as well.

2. Target: If the first rater is considered a target, then an agreement occurs if and only if another rater places an object in the same category as the first. More explicitly, let $w_{rst} = a_{rs} + b_{rt}$, then

$$E(\Lambda_3) = n \sum_{r,s,t} (a_{rs} + b_{rt}) p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t}$$

$$= n[\sum_r p_{r\cdot\cdot}(p_{\cdot r\cdot} + p_{\cdot\cdot r})];$$

$$\operatorname{var}(\Lambda_3) \approx n\{2[\sum_{r,s,t} (a_{rs} + b_{rt}) p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t}]^2$$

$$+ \sum_{r,s,t} (a_{rs} + b_{rt})^2 p_{r\cdot\cdot} p_{\cdot s\cdot} p_{\cdot\cdot t}$$

$$- \sum_r p_{r\cdot\cdot}[\sum_{s,t} (a_{rs} + b_{rt}) p_{\cdot s\cdot} p_{\cdot\cdot t}]^2$$

$$- \sum_s p_{\cdot s\cdot}[\sum_{s,t} (a_{rs} + b_{rt}) p_{r\cdot\cdot} p_{\cdot\cdot t}]^2$$

$$- \sum_t p_{\cdot\cdot t}[\sum_{r,s} (a_{rs} + b_{rt}) p_{r\cdot\cdot} p_{\cdot s\cdot}]^2\}$$

$$= n[\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot}(1 - p_{\cdot r\cdot} - p_{r\cdot\cdot})$$

$$+ \sum_r p_{r\cdot\cdot} p_{\cdot\cdot r}(1 - p_{\cdot\cdot r} - p_{r\cdot\cdot})$$

$$+ (\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot})^2 + (\sum_r p_{r\cdot\cdot} p_{\cdot\cdot r})^2].$$

3. Pairwise: An agreement occurs if and only if two raters categorize an object consistently. Thus, if we let $w_{rst} = a_{rs} + b_{rt} + c_{st}$, then

$$E(\Lambda_3) = n(\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot} + \sum_r p_{r\cdot\cdot} p_{\cdot\cdot r}$$

$$+ \sum_r p_{\cdot r\cdot} p_{\cdot\cdot r});$$

$$\operatorname{var}(\Lambda_3) \approx n[(\sum_r p_{r\cdot\cdot} p_{\cdot r\cdot})^2 + (\sum_r p_{r\cdot\cdot} p_{\cdot\cdot r})^2$$

$$+ \sum_r p_{\cdot r\cdot} p_{\cdot\cdot r})^2$$

$$+ \sum_r p_{r\cdot\cdot} p_{\cdot r\cdot}(1 - p_{\cdot r\cdot} - p_{r\cdot\cdot})$$

$$+ \sum_r p_{r\cdot\cdot} p_{\cdot\cdot r}(1 - p_{r\cdot\cdot} - p_{\cdot\cdot r})$$

$$+ \sum_r p_{\cdot r\cdot} p_{\cdot\cdot r}(1 - p_{\cdot r\cdot} - p_{\cdot\cdot r})].$$

Although these three interpretations given for w_{rst} are probably the most obvious, several other possibilities exist:

4. If $w_{rst} = 1$ when at least one nontarget rater matches the target and 0 otherwise, then w_{rst} = maximum (a_{rs}, b_{rt}).

5. If $w_{rst} = 1$ when at least one pair of raters match and 0 otherwise, then w_{rst} = maximum (a_{rs}, b_{rt}, c_{st}).

6. If w_{rst} denotes the number of matches for pairs of raters with consecutive labels, then $w_{rst} = a_{rs} + c_{st}$.

7. If $w_{rst} = 1$ when a majority of raters match and 0 otherwise, then $w_{rst} = 1$ if $a_{rs} + b_{rt} + c_{st} \geq 2$ and 0 otherwise.

Although I shall not pursue these latter definitions or extensions to more than three raters (or in general, a G-fold contingency table for G greater than three), the approach follows exactly that given above and can be carried out by the reader.

Measuring Concordance in K *Rankings*

One of the standard nonparametric data-analysis problems is discussed under the title of "Friedman's Test" or "Kendall's Coefficient of Concordance." Here, K judges assign numerical values to n objects (e.g., ranks) and our interest is in (a) testing whether the n objects can be considered equally preferable and (b) measuring the degree of concordance among the K judges. In our context, the traditional approach to both of these problems relies on a particular K-variate function $h[x_{i_1}{}^{(1)}, \ldots, x_{i_K}{}^{(K)}]$ of the form

$$h[x_{i_1}{}^{(1)}, \ldots, x_{i_K}{}^{(K)}] = \sum_{k<k'} h[x_{i_k}{}^{(k)}, x_{i_{k'}}{}^{(k')}],$$

where

$$h[x_{i_k}{}^{(k)}, x_{i_{k'}}{}^{(k')}] = [x_{i_k}{}^{(k)} - x_{i_{k'}}{}^{(k')}]^2.$$

Thus, the raw index Λ_k can be written as

$$\Lambda_k = \sum_i (\sum_{k<k'} (x_i{}^{(k)} - x_i{}^{(k')})^2).$$

When viewed in a K by n analysis-of-variance format, Λ_k is merely K times the sum of squares *within* the n columns. Furthermore, if ranks are used rather than the original observations, implying that all row sums are equal, Λ_K is simply K times the sum of squares for interaction. Thus, since Λ_K/K and the sum of squares between columns must sum to the constant total sum of squares, a test statistic and a final normalized index could be defined equivalently using either of the former two quantities. Friedman's statistic and Kendall's coefficient of concordance W are defined in terms of the sum of squares between columns, but, as we will see later, W could be obtained just as well using Λ_K/K.

Viewed another way based on the Spearman norm Γ_2, denoted here by $\Gamma_{kk'}$ for the kth and k'th sequences,

$$\Lambda_K = \sum_{k<k'} \Gamma_{kk'},$$

and using the general formulas given previously,

$$E(\Lambda_K) = \sum_{k<k'} E(\Gamma_{kk'});$$

$$\text{var}(\Lambda_K) = \sum_{k<k'} V(\Gamma_{kk'}).$$

This result is also reflected in the fact that the Γ indices are independent in pairs (cf. David & Barton, 1962, p. 218), and suggests that very simple mean and variance formulas result when the function $h(x_{i_1}{}^{(1)}, \ldots, x_{i_K}{}^{(K)})$ is *additive* with respect to the appropriate bivariate functions. Thus, similar results would hold for $\Gamma_{kk'}$ defined using Γ_1 or any other bivariate function. Moreover, it is relatively simple to propose alternative *nonadditive* functions that measure variability within a column of the K by n table (e.g., the range) that would lead to alternative raw indices of concordance.

It should be apparent at this point that the problem of nominal scale response agreement among K raters can be rephrased in a generalized Friedman context involving K sequences of n observations. Instead of using ranks, however, category labels are attached to each of the n objects by each rater.

Testing for an a Priori Order in K *Rankings*

Instead of a general hypothesis test of the Friedman type, we can also define a test procedure sensitive to a particular a priori ordering of the n objects. Such an extension can be viewed as an analogue of the target-rater agreement problem mentioned earlier. If an a priori set of weights is given by the first sequence $x_1{}^{(1)}, \ldots, x_n{}^{(1)}$, then an appropriate test statistic can be given in the form used by Page (1963) and by Pirie and Hollander (1972) based on the function

$$h[x_{i_1}{}^{(1)}, \ldots, x_{i_K}{}^{(K)}] = x_{i_1}{}^{(1)} \sum_{k=2}^{K} x_{i_k}{}^{(k)}.$$

Thus, the index

$$\Lambda_K = \sum_{i=1}^{n} x_i{}^{(1)} \sum_{k=2}^{K} x_i{}^{(k)},$$

can be interpreted as a weighted sum of column totals, where each total is defined over the last $K-1$ sequences. Typically, the weights are integers from 1 to n, and the values $x_i{}^{(k)}$ for $k \geq 2$ are ranks (Page, 1963) or normal scores (Pirie & Hollander, 1972). The mean and variance formulas follow directly from the previous expressions, or alternatively, since Λ_K can be defined by the sum of the $K-1$ independent terms

$$\sum_{i=1}^{n} x_i{}^{(1)} x_i{}^{(k)}, \quad \ldots, \quad \sum_{i=1}^{n} x_i{}^{(1)} x_i{}^{(K)},$$

the mean and variance can be obtained by the usual moment formulas for linear combinations of random variables. Obviously, the formulas for the mean and variance of each individual term can be found by the relatively simple expressions used in the bivariate function examples based on two sequences.

Significance Testing

Although some proofs of asymptotic normality exists for various special cases of the index Λ_K (cf. David & Barton, 1962; Hoeffding, 1951), as well as proofs for the convergence to a chi-square random variable for related statistics such as Friedman's (see Lehmann, 1975), all these approximations are of varying adequacy depending on the size of K, n, the scoring function, and the patterning of entries in the various sequences. In some cases, such as the Page test just discussed, the normal approximation is easy to demonstrate and is

probably very good if K is reasonably large. In this latter case, the distribution of the index is generated by a sum of independent random variables, and each individual term is itself asymptotically normal under mild regularity conditions. Most ideally, however, any observed index would be so extreme that a simple Chebyshev inequality in conjunction with the available moments would be sufficient to guarantee significance of the index at some adequate level. Alternatively, approximate permutation tests, such as those discussed by Hope (1968), Cliff and Ord (1973), Edgington (1969), and others, could be used. Given the continuing reduction in computer costs, this latter alternative of sampling from the complete distribution may be the most appropriate to follow in the years to come (see Hubert, 1979, for an illustration of how an approximate permutation test could be carried out).

Indices

Although the raw index Λ_K is sufficient for hypothesis testing, researchers will typically desire some normalized version of Λ_K as a final measure of concordance or agreement. Many different normalizations are possible, but several forms appear continually in the literature. For instance, if it is assumed that Λ_K is nonnegative and that large values of Λ_K denote greater degrees of *concordance* (where this term is being used generically), two general expressions can be given as

$$\Lambda_K/\text{maximum } \Lambda_K; \tag{3}$$

$$[\Lambda_K - E(\Lambda_K)]/[\text{maximum } \Lambda_K - E(\Lambda_K)]. \tag{3a}$$

If the "keying" of Λ_K were in the opposite direction and were denoted by Λ'_K, these two indices would be given as

$$1 - \frac{\Lambda'_K}{\text{maximum } \Lambda'_K}; \tag{4}$$

$$1 - \frac{\Lambda'_K}{E(\Lambda'_K)}. \tag{4a}$$

The indices in Expressions 3 and 4 and in Expressions 4 and 6 are analogues, and to transform one expression to the other, the raw index Λ'_K in Expressions 5 and 6 is rewritten as $\max \Lambda_K - \Lambda_K$. Here, Λ_K is the raw index used in Expressions 3 and 4 and we note that since Λ_K is nonnegative, maximum Λ'_K = maximum Λ_K.

The indices in Expressions 3 and 4 lie between 0 and 1; those in Expressions 3a and 4a are bounded above by 1 but may take on negative values as well. An example of Expression 4 would be Kendall's coefficient of concordance W based on the index Λ_K defined as K times the sum of squares for interaction. The form given by Expression 3a is Cohen's (1968) general expression for his index of nominal scale response agreement kappa. Finally, the measure in Expression 4a provides the basis for one version of Spearman's rank order correlation coefficient based on Γ_2 as well as for the general degree-1 statistic introduced by Hildebrand, Laing, and Rosenthal (1977) in a related nominal scale response-agreement context, using arbitrary weights on the cells of a contingency table.[2]

Although a host of different normalized indices are possible (cf. Hubert & Levin, 1976), the forms given by Expressions 3a and 4a appear to be of continuing importance in the behavioral sciences because they are "corrected for chance." It is important to remember, however, that any normalization is more or less arbitrary, and hypothesis testing can be carried out using only the raw index Λ_K.

Discussion

There are a number of directions in which the preceding material can be extended. For example, instead of permuting the entries within the rows of the K by n table, suppose the elements can be rearranged throughout the table. This inference model has been discussed in the context of nominal scale response agreement (Hubert, in press), and it has been pointed out that when K is 2, the index Γ_2 provides an unnormalized intraclass correlation.

In addition to alternative inference models, other applications of the sequence-comparison

---

[2] In many cases it is traditional to define maximum Λ_K or maximum Λ'_K from some ideal case, for example, untied ranks, and to treat this quantity as a constant irrespective of the configuration of ties in the K by n table.

notion could be developed. For instance, Cochran's Q statistic and McNemar's test for correlated proportions are really special cases of Friedman's test (see Lehmann, 1975), and thus, these techniques could be rephrased within the K sequence-comparison framework. Also, a variant on the type of degree-1 confirmatory analysis developed by Hildebrand, Laing, and Rosenthal (1977) for a bivariate table could be extended to a K-way contingency table by using the sequence-comparison interpretation relevant to nominal scale response agreement.

What is important in all of these applications or extensions is the recognition of problem commonality. The field of nonparametric statistics is very broad and diversified, and consequently, general organizing principles may be of immense pedagogical help to a student attempting to organize the field into a coherent cognitive structure.

Choosing Between Predictable and Unpredictable Shock Conditions: Data and Theory

Pietro Badia
Bowling Green State University

John Harsh
State University of New York at Geneseo

Bruce Abbott
Bowling Green State University

This article reviews the literature on predictability and describes the factors that affect choice. Particular emphasis is given to the reliability of basic findings, including replications and failures to replicate. Behavioral measures related to choice are also reviewed, and some physiological correlates of predictable and unpredictable shock are noted. The data allow several firm conclusions to be drawn regarding preference, notably that (a) rats (albino, hooded, male, female) prefer predictable shock conditions; (b) they prefer predictable conditions whether shock is avoidable, escapable, or inescapable, and whether it is scrambled or unscrambled grid shock; (c) this preference occurs with different procedures, apparatus, and shock delivery systems, such as water electrodes or electrodes attached to the tail, back, ears, or pubis bone; (d) fish and birds also prefer the signaled condition; and (e) although the preference is robust, it is affected by shock intensity, signal duration, intershock intervals, amount of training, and the dependability of shock-free periods. Other factors that may affect preference are also noted. Finally, the theoretical views of conditioned reinforcement, of information, of preparation, and of safety are evaluated, and their strengths and weaknesses are described.

Research over the last two decades reveals clearly that preference for schedules of both positive reinforcers (e.g., food) and negative reinforcers (e.g., shock) is governed by more than reinforcer-related variables such as rate, magnitude, and duration. Subjects confronted with a choice between a predictable versus an unpredictable shock or food condition most often choose the predictable one, even though all other factors are constant.[1] This result is perhaps not surprising, since predictability may afford the subject the opportunity to prepare for the reinforcer in a way that minimizes its aversiveness or maximizes its attractiveness. We argue, however, that despite its intuitive appeal, this "preparation" hypothesis does not adequately account for current data. We also examine the strengths and weaknesses of alternative explanations.

In our discussion, we focus on predictable and unpredictable shock conditions with nonhuman subjects. We first review studies in which animals are given a choice between

[1] There are times in the appetitive situation when subjects choose an unpredictable condition over a predictable one (e.g., Herrnstein, 1964). In Herrnstein's study and in others, animals consistently preferred a variable interval schedule for food over a fixed interval schedule for food of equal value. Such findings suggest that predictability based on periodicity and predictability based on signaling may have different properties or that aperiodicity may have effects other than those produced by lack of signaling.

predictable and unpredictable shock; we discuss the basic phenomenon and some factors that affect the strength of preference. Then we review some of the issues concerning basic findings, research methods, replications, and failures to replicate. In a separate section, we note some behavioral and physiological correlates of predictable and unpredictable shock. Finally, we assess the different theoretical interpretations that have appeared in the literature on choice and predictability. Specifically, we assess the preparation hypothesis, the discriminative stimulus ($\overline{\mathrm{CS}}$) or safety hypothesis, the information hypothesis, and the conditioned reinforcement hypothesis.

Initial Data and Theory

Earlier theorizing about the factors controlling behavior in aversive situations originated in studies focusing on the properties acquired by stimuli preceding shock. One commonly held view is that the pairing of previously neutral stimuli with an aversive stimulus, such as shock, results in conditioned aversiveness (e.g., Mowrer, 1947; Schoenfeld, 1950). This view, which appeals to a conditioned reinforcement process, has played a particularly important role in theoretical accounts of avoidance, escape, and punishment behavior. With respect to choosing between signaled and unsignaled shock, this view predicts that schedules of unsignaled shock will be less aversive than (preferred over) schedules of signaled shock because the latter include the aversive properties of shock plus those of the signal.

Coppock (1954) reported one of the first studies related to preference and to the properties acquired by stimuli preceding aversive events. During training, rats were exposed to either signaled (cue preceded shock) or unsignaled (cue occurred during shock) tail shock while in a restraining apparatus. Shocks were omitted during a testing phase, but by turning its head to one side, the subject could produce the cue previously associated with shock. The analysis of head movement toward the signal suggested to Coppock that stimuli preceding shock acquire greater control over responding than do stimuli occurring during shock. According to Coppock, these findings were unexpected, since the shock signal should have acquired conditioned aversive properties. Coppock concluded that contrary to conditioned reinforcement theory, stimuli preceding shock can acquire positive reinforcing properties but he gave no rationale for how this occurred.

A few years later, Knapp, Kause, and Perkins (1959) gave rats a choice between immediate and delayed shock (Experiment 1), using a T maze. Their subjects preferred the immediate condition. Knapp et al. argued that their findings could not be accounted for by existing conditioned-reinforcement theory, which in this case would predict that painful stimuli immediately following a response should become more aversive than the same stimuli when delayed. In Experiment 2, they gave subjects a choice between delayed shock preceded by a signal and delayed shock followed by a signal. The subjects preferred the signal–shock condition. Arguing again that conditioned reinforcement theory was inadequate to explain their findings, Knapp et al. suggested the preparatory-response hypothesis developed earlier by Perkins (1955). In brief, this hypothesis states that signals preceding appetitive or aversive events allow the organism to prepare for the receipt of stimulation. Such preparation allegedly maximizes the reinforcing properties of appetitive events or minimizes the aversive properties of painful events.

About a year later, Mowrer (1960) described two studies conducted by Mohammed Akhtar. In both studies, signaled or unsignaled shocks were delivered to a grid floor at irregular intervals. If the subjects faced in one direction, they received signaled shocks; if they faced in the other direction, shocks were unsignaled. Shocks were avoidable or escapable. Four of five rats in the first experiment preferred the signaled avoidable shock, and all four subjects in the second experiment preferred the signaled shock condition. Mowrer's interpretation of these results anticipated much of the theorizing that later developed and that is now referred to as the safety hypothesis. In de-

scribing the characteristics of the signal condition, Mowrer stated that a subject "could sharply discriminate between brief periods when it was in real danger (i.e., when the tone was on) and the rest of the time when the rat was perfectly safe and could well afford to 'relax'" (p. 194). In answer to why the rats might seek out a warning signal preceding aversive shock, he stated: "They did not seek the warning signal as such; instead, they sought the situation in which the warning signal occurred, because . . . they experienced less total fear here than in the no-signal situation" (p. 196). Similar interpretations were subsequently offered by others (Badia, Culbertson, & Lewis, 1971; Denny, 1971; Lockard, 1963; Seligman, 1968). The development of various theoretical positions is discussed in detail later.

A theoretical view stressing the importance of information emerged at about the same time that Mowrer's views were made known (Berlyne, 1960). In brief, Berlyne suggested that uncertainty about the occurrence of biologically significant events creates a state of conflict and that stimuli that reduce this conflict (i.e., provide information) are rewarding. This "uncertainty reduction" view clearly predicts that preshock stimuli should be sought out for their informational value. Therefore, the data that were compatible with the views of Coppock (1954), Mowrer (1960), and Perkins (1955) were also compatible with those of Berlyne (1960).

The stage was set for assessing how well the various hypotheses of conditioned reinforcement, preparation, uncertainty, and safety could account for the accumulating data on preference for predictable versus unpredictable shock. Inevitably, subsequent tests involved different procedures and different parameter values, raising both methodological and empirical issues. Some of these remain unresolved, and heated arguments have appeared in the literature (Badia & Harsh, 1977a, 1977b; Biederman & Furedy, 1976b; Harsh, 1978).

What does the literature reveal regarding the phenomenon of choice? Is the phenomenon reliable? Is it robust? What are the boundary conditions? What theoretical interpretations are most favored?

Literature Review

How Reliable Is the Phenomenon?

Since the early studies of Coppock (1954), Knapp et al. (1959), and Akhtar (in Mowrer, 1960), numerous studies have confirmed the preference for signaled over unsignaled shock schedules. A reliable and robust preference for signaled shock has appeared with a variety of choice procedures, shock delivery methods, and species.

Some of the earliest research specifically directed toward the question of preference concerning signaled or unsignaled shock was performed by Perkins, Levis, and Seymann (1963) and by Lockard (1963). Perkins et al. ran rats and found that 14 of the 16 subjects spent about 70% to 80% of the time on the signaled shock side of the shuttle box. When the conditions were reversed, however, a reversal in preference did not occur. Perkins et al. attributed this failure to reverse to the fact that there were only three test days. Reversal was not a problem in a subsequent study by Perkins, Seymann, Levis, and Spencer (1966). Lockard's (1963) results were similar to those of Perkins et al. After 12 sessions, her subjects were spending about 90% of the trials on the signaled side of the apparatus. Control subjects presented with a random signal and shocks were indifferent. Lockard demonstrated that neither signals alone nor random signals and shocks were able to maintain a preference for the signaled condition; a strong preference emerged only when signals preceded shock. Both Perkins et al. and Lockard used unscrambled shock.[2]

Lockard (1965) continued her earlier in-

[2] With unscrambled grid shock, the charge on each grid bar is fixed and alternate grid bars carry opposite charges (positive or negative). With scrambled shock, the charge on each grid bar is rapidly alternated so that in each cycle it is momentarily the opposite of the charge on other bars. Scrambling the shock is designed to eliminate unauthorized avoidance responses (e.g., standing on grid bars of the same polarity) that sometimes occur with unscrambled shock.

vestigation of preference using two different shock (unscrambled) intensities (.221 mA or .236 mA) and four signal–shock intervals (5 sec, .5 sec, 0 sec, or random). Four groups had the same level of shock for both compartments, and four groups had a 7% higher shock level for the signaled side. Only subjects receiving equally intense shocks on both sides in the .5-sec or 5-sec groups tended to prefer the signaled condition. Subjects with the 0-sec signal–shock interval performed the same as the random-interval group did. Also, the level of preference was far weaker than it had been in the first study (Lockard, 1963). One reason why Lockard failed to replicate the high preference found in her earlier work may be that the shock levels were too low in the later study. Other variables were examined by Perkins et al. (1966). They used unscrambled shock with a variety of intershock intervals, shock durations, and signal durations. Only a brief summary of their extensive findings can be given here. In particular, they showed that parameter values were important determiners of choice for the signaled condition. The most marked preference occurred with 12 to 60 shocks per hour, an 18-sec signal duration, and either a .5-sec or 5-sec shock. When the signal duration was decreased, preference was weaker. Preference was also weaker when the intershock interval resulted in 2 shocks per hour. An interesting and important part of their study was the delivery of shock through ear clips for one group (Experiment 5). The results of this experiment will be described later in the section on shock delivery systems.

A replication of Perkins et al. (1966) was performed by Furedy and Walters (Note 1) but with an added condition. Half of their subjects received scrambled shock, the other half, unscrambled shock. Subjects receiving scrambled shock spent a higher percentage of time on the signaled side than did subjects receiving unscrambled shock (80% vs. 65%). However, because of equipment failures and because the typical learning curve for preference was not found, the authors doubted the validity of their findings. They performed a second experiment with improved equipment and found that subjects given either scrambled or unscrambled shock preferred the signaled condition. However, the preference was stronger with unscrambled shock. A clear learning curve was also observed over the first 2 days similar to that reported by other researchers. The data of Furedy and Walters suggested that scrambling may have some effect but that it clearly does not eliminate preference for the signaled condition.

Several other studies using a shuttle box and scrambled shock reported that subjects preferred a signaled shock condition over an unsignaled one, and preference was marked for most conditions (Frankel & Vom Saal, 1976; Gliner, 1972; Hymowitz, 1973). Gliner's study also assessed the effects of shock intensity on choice and the effects of signaling shock on the physiology of the organism. He found that a marked preference for the signaled condition developed for both high- and low-shock-intensity subjects, but the preference developed more slowly for subjects receiving high-intensity shock. Also, he found less physiological deterioration when shock was signaled, a phenomenon we describe in more detail later.

Observing Response Procedure and Choice

Except for the early studies of Coppock (1954), Knapp et al. (1959), and Akhtar (in Mowrer, 1960), all studies reviewed thus far used a shuttle box procedure to assess choice, and the subjects preferred the signaled condition. Other procedures have been used with similar results. An extensive series of experiments has been performed using an operant changeover procedure (e.g., Badia & Culbertson, 1972). With this procedure, baseline responding on a changeover lever is recorded while a subject is being exposed (training) to the different conditions of the experiment. Shocks are usually presented noncontingently on some schedule, and different correlated stimuli identify the signaled and unsignaled conditions. Following training, subjects are given an opportunity to choose the condition in which they prefer to remain (testing). Subjects are placed in an imposed condition of either signaled or unsignaled shock, and a lever press (changeover re-

sponse) changes the condition to the opposite one for a fixed period of time (e.g., 1 min.). At the end of this fixed period, the initial imposed condition is then reinstated and remains in effect until another changeover response occurs. This procedure is similar to the one introduced by Wyckoff (1952).

The first preference studies using the changeover procedure were reported by Badia, Culbertson, and Lewis (1971) using signaled and unsignaled avoidable shock, and by Badia and Culbertson (1972) using either signaled or unsignaled escapable (Experiment 1) or inescapable (Experiment 2) shock. Subjects often spent 90% or more of the time in the signaled condition, and it did not matter whether shock was avoidable, escapable, or inescapable. The strong preference for the signaled condition was shown within each subject repeatedly over a series of acquisition and extinction conditions. Three different extinction conditions were also given to identify stimuli controlling the preference. Under extinction conditions, a response produced (a) the stimulus (signal) identifying the shock period, (b) the stimulus identifying the shock-free period, or (c) neither stimulus. Changeover responding was greatest under the second condition, intermediate under the first, and least under the third. An exact replication of Badia and Culbertson's (1972) study was undertaken by Lewis and Gardner (1977), and the data obtained were virtually identical.

Another series of experiments assessed the robustness of the phenomenon (Badia, Coker, & Harsh, 1973; Badia, Culbertson, & Harsh, 1973). Subjects in each experiment were initially given a choice between signaled and unsignaled shock schedules, with shock parameters equal in the two conditions. Then density, duration, or intensity of signaled shock was systematically increased over that of unsignaled shock. Subjects chose the signaled condition over the unsignaled one when shock parameters were equal and continued doing so when signaled shocks were up to four times more dense, four to nine times longer, or two to three times more intense than unsignaled shocks. A control condition for the shock density study showed that subjects would choose a lower density shock schedule over a higher one when all shocks were unsignaled. However, choice of the lower density schedule was eliminated by signaling the shocks on the higher density schedule.

Most experiments testing the effects of predictable versus unpredictable aversive shock conditions have employed warning signals to make shock and shock-free periods predictable. One can also increase predictability by making the occurrence of shocks temporally regular. Badia, Harsh, and Coker (1975) assessed the relative effectiveness of temporal regularity and signaling on preference using the changeover procedure. Subjects chose between fixed-time (FT) and variable-time (VT) shock schedules under several signaling conditions: (a) unsignaled FT versus unsignaled VT shock, (b) signaled FT versus signaled VT shock, and (c) unsignaled FT versus signaled VT shock. Subjects chose the FT over the VT shock schedule when both were unsignaled and again when both were signaled. They chose the VT over the FT schedule only when the VT shocks were signaled and the FT shocks unsignaled.

Shock Delivery Systems and Choice

Some authors have been critical of the methods used to study signaled and unsignaled shock (Biederman & Furedy, 1976b). One of the major criticisms is that preference for the signaled condition occurs only when shock is modifiable, that is, only when subjects are able by means of postural adjustment on the shock grid to partially or totally avoid the shock or to minimize its aversiveness. The criticism is of obvious import to both theoretical and methodological issues. If true, it would bear directly on the development of theoretical statements. A number of studies relate directly to the alleged problem of differential shock modification. Various procedures have been used to eliminate the problem or to monitor the extent to which it might occur. To ensure that subjects do not differentially modify the shock, some investigators have delivered shock through ear clips (Perkins et al., 1966), through tail electrodes (Coppock, 1954; Miller, Daniel, & Berk, 1974; Miller, Marlin, & Berk, 1977),

through implanted electrodes (Cotsonas, 1972; Griffin, Honaker, Jones, & Pynes, 1974), or through water electrodes (Fisher & Badia, 1975). The use of attached electrodes makes it virtually impossible to modify shock through unauthorized escape or avoidance responses. Other researchers have monitored and measured the amount of shock received by subjects when shock was signaled and when it was unsignaled (Lockard, 1963). A consistent pattern emerges from this research.

The first experiment using surface electrodes, in this case ear clips, was Experiment 5 of the Perkins et al. (1966) study. These investigators found that 13 of the 16 subjects preferred the signaled condition on Day 1. Of the 10 subjects completing the second day of testing with the ear clips still attached, 5 preferred the signaled condition. For the 3 subjects completing 3 days and 2 subjects completing 4 days of testing, the preference for the signal condition was marked. Clearly, the subjects of Perkins et al. preferred signaled over unsignaled shock conditions even with shock applied directly to the body. Other studies using tail shock have been reported by Miller et al. (1974) and Miller et al. (1977). The subjects in these studies also chose the signaled over the unsignaled condition and in some cases over successive reversals.

Findings similar to those for tail shock have been reported with back electrodes by Cotsonas (1972). Brass safety pins were inserted into the lower back in the first part of the experiment. Two subjects were tested, and both preferred the signaled condition; only one later showed a reversal when the conditions were changed. In the second part of the experiment, eight subjects were run. Seven of the eight preferred the signaled condition; all seven succeeded in three reversal conditions. The next experiment kept subjects in the same condition for 15 days prior to reversing for 15 days. The subjects did not continue to remain on the signaled side. The latter outcome is possibly due to problems arising from chronically implanted electrodes. Other investigators using grid shock have not found any attenuation of preference over time.

The generality of the preference for signaled over unsignaled shock in terms of shock delivery systems and in terms of species was increased by Griffin et al. (1974) and by Fisher and Badia (1975). Griffin et al. implanted electrodes in pigeons by attaching them to the pubis bone and gave their subjects a choice between the two shock conditions. Two pigeons were run using a procedure similar to that of Badia and Culbertson (1972). Variability tended to be high; nevertheless, one subject clearly changed to the signaled condition, and the other showed a similar but less marked trend under the high-intensity shock condition. Fisher and Badia (1975) used the changeover procedure with goldfish in a shuttle box. Water electrodes distributed shock evenly throughout the shuttle box. The subjects preferred the signal condition, and their performance was similar to that of rats tested under similar conditions, including performance under the three different extinction conditions used by Badia and Culbertson (1972).

Others have used different procedures to determine if signaled shock was more modifiable than unsignaled shock. These studies monitored the development of skeletal preparatory responses to the signal (Badia & Abbott, in press; Biederman & Furedy, 1973, Experiment 1; Biederman & Furedy, 1976b; Furedy & Biederman, 1976; Lockard, 1963; Marlin, Berk, & Miller, 1978; Abbott & Badia, Note 2). Lockard used a pen recorder to monitor when subjects avoided unscrambled shock. Only about 1.4% of the shocks were avoided; of these, equal numbers were avoided by the signaled shock group and random signal group. Lockard also failed to detect any systematic differences in the postural behavior of the two groups.

Different results were obtained in a series of experiments by Biederman and Furedy in which the current flow through the subject was monitored during shock. Biederman and Furedy (1973, Experiment 1) found that the degree of unscrambled shock attenuation correlated weakly (.40) but significantly with the degree of preference for the signaled condition. Subjects receiving scrambled grid shock or tail shock showed no attenuation and no preference. Furedy and Biederman

(1976, Experiment 3) obtained similar results using Lockard's (1963) shuttle box procedure with the training phase omitted. Unscrambled shock was used. Modification of shock was again observed, and there was a relation between degree of modification and degree of preference for the signaled condition.

The reports of Biederman and Furedy seem to provide evidence that modification of shock can be an important determinant of preference. However, the studies may be faulted. First, the findings provide no direct evidence on differential modification of shock between the signaled and unsignaled conditions. Separate modification scores were not reported. If preference for the signaled condition is related to better avoidance or reduction of shock in the signaled condition, this needs to be demonstrated. Second, even if one is willing to accept the observed correlation between preference and overall modification as suggestive of differential modification, there is another problem. Biederman and Furedy used exceptionally long shocks (5 sec), whereas most researchers used much briefer shocks (e.g., .5 sec; see Table 1) specifically to minimize the problem of avoidance. Attenuation, if it does occur, is more likely with long rather than short shocks. It may be that shock attenuation with long durations is a sufficient but not a necessary condition for preference to emerge. Another problem relates to training, that is, the exposure of subjects to the signaled and unsignaled conditions prior to their being given a choice. This phase provides subjects the opportunity to associate each condition with its correlated stimulus. Biederman and Furedy obtained their results only after training was eliminated. Other researchers have found that considerable experience with the signaled and unsignaled conditions is necessary before subjects acquire a preference for the signaled condition (e.g., Badia & Culbertson, 1972). The parameters chosen by Biederman and Furedy would appear to minimize a preference for signaled shock based on associative factors and maximize the potential for differential modification of signaled and unsignaled shocks. Therefore, Biederman and Furedy may be studying a different phenomenon. A chronological listing of studies investigating choice under signaled and unsignaled conditions is located in Table 1. The listing includes procedures used, parameters varied, and results obtained.

Evidence suggesting that differential modification of shock may occur was reported by Marlin et al. (1978) and was based on observation of subject postures during signals and during the intertrial interval but not during shock. Following preference testing in which the subjects chose the 100% signal condition over one in which signals preceded shock only 80% of the time, each subject was observed across 20 shocks. The subjects were found to be rearing at shock onset 64% of the time and appeared to avoid 6.5% of the shocks as indicated by the lack of response. The incidence of full rearing (front paws off the grid, body axis more than 45° from horizontal) was only marginally greater during signals than in their absence (30% and 29%, respectively), but partial rearing (body axis less than 45° from horizontal) occurred far more frequently during signals than during signal absence (59% and 3%, respectively). Asserting that rearing responses modify shock, Marlin et al. concluded that scrambled-grid shock allows shock modification and should be replaced with a fixed-electrode preparation to exclude its possibility. Their own fixed-electrode studies (e.g., Miller et al., 1977) convinced them, however, that the preference for signaled shock is not solely determined by modification.

Although the Marlin et al. (1978) results are suggestive, the lack of interrater reliabilities, the failure to use a blind procedure to rate modification to signaled and unsignaled shocks, and the failure to document a relation between observed postures on the grid and actual modification of shock reduce the value of these data. A study that is not open to these criticisms was conducted by Badia and Abbott (in press). The changeover procedure was used to assess preference for signaled over unsignaled shock, and all parameters were similar to previous studies (e.g., Badia & Culbertson, 1972). Additional equipment permitted the measurement of current flow through the subject. The study revealed

Table 1
Studies Involving Choice Between Signaled and Unsignaled Shock Schedules Reported Between 1959 and 1978

Investigator	Choice procedure	Parameter	Test session	Results
Knapp, Kause, & Perkins (1959; Experiment 2)	T maze	Unscrambled, .7-sec, 60-V shock; 30-sec signal	50 (8 trials/day)	80–90% of free-choice trials to signal side after 21 sessions
Akhtar (cited in Mowrer 1960)	Orientation in revolving cage	Grill floor, VT 90-sec shock (escapable and avoidable); signal duration not specified	Multiple approximately 25-min sessions	4 of 5 subjects chose signaled schedule
Lockard (1963)	Shuttle box	Unscrambled, 2-sec, .28-mA, VT 1.9-min shock; 5-sec signal	12 1-hour sessions	90% of trials on signaled side after 12 sessions
Perkins, Levis, & Seymann (1963)	Shuttle box	Unscrambled, .5-sec, 500-V, VT 5-min shock; 3-sec signal	6 10-hour sessions	75–80% of time on signaled side; unsuccessful reversal
Lockard (1965)	Shuttle box	Unscrambled, VT 1.9-min. 221-mA or .236-mA shock (duration not specified); signal duration varied	12 1-hour sessions	Preference related to conditions; weak preference at best
Perkins, Seymann, Levis, & Spencer (1966)	Shuttle box	Unscrambled or direct, 500-V shock, duration, ITI, and distribution varied; signal duration varied	6–9 10-hour sessions	Up to 90% of time on signaled side; preference related to conditions; successful reversals
Furedy & Walters (Note 1; Experiment 2)	Shuttle box	Scrambled and unscrambled, 5-sec, mA, VT 2-min shock; 3-sec signal		Preference for signaled side stronger with unscrambled shock
Badia, Culbertson, & Lewis (1971)	Changeover	Scrambled, .75-mW or 1-mA, .32-sec avoidable shock; 5-sec signal	Multiple 6-hour sessions	All subjects changed to signaled schedule
Badia & Culbertson (1972)	Changeover	Scrambled, .75-mW, escapable (Experiment 1) or inescapable (Experiment 2), .5-sec, VT 2-min shock; 5-sec signal	Multiple 6-hour sessions	All subjects changed to signaled schedule
Gliner (1972)	Shuttle box	Scrambled, 2-sec, VT 2.5-min shock (intensity varied); 10-sec signal	5 6-hour sessions	Signaled shock preferred by both high- and low-intensity-shock groups
French, Palestino, & Leeb (1972)	Shuttle box	Unscrambled, <1-mA, 1-sec, VT 90-sec shock; signal duration varied	Multiple 1-hour sessions	Preference for signaled shock by all groups
Cotsonas (1972; Experiments 2 & 3)	Shuttle box	Direct, .5-sec, 2.8-mA, VT 1-min shock; 3-sec signal	Multiple 90-min sessions	Preference for signaled schedule evident, some difficulty with reversals

Table 1 (*continued*)

Investigator	Choice procedure	Parameter	Test session	Results
Badia, Coker, & Harsh (1973)	Changeover	Scrambled, .5-sec, 75-mW, VT schedule varied; 5-sec signal	Multiple 6-hour sessions	Preference for signaled schedule even when signaled shocks 2–8 times more frequent
Badia, Culbertson, & Harsh (1973)	Changeover	Scrambled, VT 2-min shock duration and intensity varied); 5-sec signal	Multiple 6-hour sessions	Preference for signaled schedule even when signaled shocks were up to 9 times longer and 6 times stronger
Hymowitz (1973)	Shuttle box	Scrambled, .5-sec, .4-mA, VT 65-sec shock; 5-sec signal	10 30-min sessions	Up to 80% of time on signaled side after 4 sessions
Biederman & Furedy (1973)	Concurrent chain schedule	Unscrambled, scrambled, or tail-shock, 5-sec, 1.0-mA, VT 45-sec shock; 5-sec signal	1 approximately 4-hour session	Preference for signals with unscrambled shock only
Miller, Daniel, & Berk (1974)	Shuttle box	Direct, .5-sec, .4-mA, VT 2-min shock; 10-sec signal	30–50 3-hour sessions	Clear preference for signaled schedule with reversals
Harsh & Badia (1974)	Changeover	Scrambled, .5-sec, 2-mA, VT 12-min shock; 60-sec signal	Multiple 3-hour sessions	Preference for signaled schedule
Griffin, Honaker, Jones, & Pynes (1974)	Changeover	Direct, .5-sec, 60–80-V, VT 90-sec shock; 5-sec signal	Multiple 3-hour sessions	Pigeons preferred signaled schedule, although considerable variablity
Fisher & Badia (1975)	Changeover	Direct, .5-sec, 8-V, VT 2-min shock; 5-sec signal	Multiple 90-min sessions	All fish preferred signaled schedule
Arabian & Desiderato (1975)	Shuttle box	Scrambled, .5-sec, 2-mA shock; 5-sec signal	10 sessions	See text
Badia, Harsh, & Coker (1975)	Changeover	Scrambled, .5-sec, .8-mA, FT or VT 1-min shock; 5-sec signal	Multiple 6-hour sessions	Preference for predictable shock schedules
Harsh & Badia (1975)	Changeover	Scrambled, .5-sec, VT 2-min shock; 5-sec signal	Multiple 6-hour sessions	Choice for signaled schedule related to shock intensity
Crabtree & Kruger (1975)	Shuttle box	Scrambled, 2-sec, 110-V, VT 2-min shock; signal duration varied	1 12-hour session	No preference observed
Harsh & Badia (1976)	Changeover	Scrambled, .5-sec, .75-mW shock; 30-sec signal	Multiple 6-hour sessions	Choice related to average ITI
Badia, Harsh, Coker, & Abbott (1976)	Changeover	Scrambled, .5-sec, 75-mW shock; 5-sec signal	Multiple 6-hour sessions	Choice related to $p(US \mid CS)$ and $p(US \mid \overline{CS})$

(*table continued*)

Table 1 (*continued*)

Investigator	Choice procedure	Parameter	Test session	Results
Furedy & Biederman (1976)	Shuttle box	Scrambled or unscrambled, 5-sec, .6-mA, VT 2-min shock; 3-sec signal	2 3-hour sessions	No preference with pretraining; without pretraining preference obtained with unscrambled shock only
Biederman & Furedy (1976a)	Changeover	Scrambled, .5-sec, 75-mW, VT 2-min shock; 5-sec signal	Multiple 6-hour sessions	Only 1 of 16 subjects clearly preferred signaled schedule
Biederman & Furedy (1976c)	Shuttle box	Scrambled, 5-sec, .6-mA, VT 2-min shock; 3-sec signal	50 3-hour sessions	Grouped data indicated no preference
Frankel & Vom Saal (1976)	Shuttle box	Scrambled, 1-sec, .5-mA, VT 2-min shock; 12-sec signal	4 10-hour sessions	Subjects spent greater time under signaled conditions
Abbott & Badia (in press)	Changeover	Scrambled, .5-sec, 1-mA, VT 120-sec shock; signal duration varied	Multiple 6-hour sessions	Preference for the signaled condition varied strongly with signal duration
Abbott & Badia (Note 2; Experiment 3)	Changeover	Scrambled, .5-sec, 75-mW or 1.0-mA, VT 2-min shock; 5-sec signal	Multiple 6-hour sessions	Grid contact time equal with signaled and unsignaled shock; choice for former
Collier (1977)	Shuttle box	Scrambled, .75-sec, 58-V, VT 6.7-min shock; 10-sec signal	5 20-min sessions	See text
Miller, Marlin, & Berk (1977)	Shuttle box	Direct or scrambled, .5-sec, intensity varied, ITI varied shock; 5-sec signal	Multiple 1.5-, 2-, or 4-hour sessions	Preference related to parameters; most subjects strongly preferred the signaled condition
Lewis & Gardner (1977)	Changeover; concurrent bidirectional changeover	Scrambled, .5-sec, 75-mW, VT 120-sec shock; 5-sec signal	Multiple 6-hour sessions	All subjects preferred the signaled condition (changeover), but only experienced subjects preferred the signaled condition in the bidirectional procedure
Safarjan & D'Amato (1978)	Changeover	Scrambled, .5-sec, .8-mA, VT 1-min shock; 5-sec signal	Multiple 4-hour sessions	Preference for the signaled condition related to the dependability and duration of the shock-free period

Note. VT = variable time; ITI = intertrial interval; FT = fixed time; US = unconditioned stimulus; CS = conditioned stimulus. All subjects are rats unless otherwise indicated.

that whether shock was signaled or unsignaled made no difference in the duration of contact with the grid bars. If anything, there was a suggestion that 10 of the 12 subjects actually received slightly longer shock durations when shock was signaled. Also of interest were oscilloscope tracings. These tracings indicated that the subjects were rapidly making and breaking grid contact during shock primarily because of running. Such activity permits reduction in grid-contact time for both signaled and unsignaled conditions, but it does not permit the kind of response that would allow precise control of current flow. We should also note that the Badia and Abbott findings confirm those reported earlier by Lockard (1963).

Conclusion

Based on this portion of the literature review, a number of firm conclusions are warranted. Clearly, organisms prefer signaled over unsignaled shock conditions, whether shock is avoidable, escapable, or inescapable. Preference for the signaled condition has occurred in rats, in pigeons, and in fish. When the conditions of the experiment are reversed, preference has also reversed, although an occasional failure to reverse with reversed conditions has been noted.

With rats, a preference for the signaled condition has been found with both males and females, and with hooded and albino animals. The same results have been reported with different apparatus and different procedures. A preference for the signaled condition develops whether shock is scrambled or unscrambled and with various shock delivery systems or surface electrodes, such as electrodes attached to the tail, to the back, to the ears, or to the pubis bone, or with water electrodes. In addition, studies measuring the duration of scrambled shock received by subjects under signaled and unsignaled conditions suggest that differential shock modification, shock avoidance, and decreased shock duration are not necessary conditions for preference. Finally, we can conclude that the preference is robust in that subjects prefer longer, stronger, and more dense signaled shock over shorter, weaker, and less dense unsignaled shock.

Factors Affecting Preference

There seems to be little question that subjects prefer signaled shock conditions and for reasons other than those related to shock modification. We now discuss the factors that strengthen or weaken preferences.

One factor affecting the strength of preference is shock intensity. Harsh and Badia (1975) used constant-current scrambled shock ranging in intensity from .15 mA to 1.0 mA, in steps of either .15 mA or .20 mA. They found that the amount of time spent in the signaled condition varied systematically with shock intensity over the lower and middle range of intensities used. Subjects did not choose the signaled condition at low shock intensities.

Another factor demonstrated to affect choice is the average intershock interval (Harsh & Badia, 1976). These investigators used a constant-wattage scrambled shock of .5 sec over six variable-time intershock intervals and a constant 30-sec signal. The intershock intervals averaged 510 sec, 270 sec, 150 sec, 90 sec, 60 sec, and 45 sec. Choice of the signaled condition was directly related to the average intershock interval for six of the eight subjects in that short intershock intervals weakened preference, and long intershock intervals strengthened it. However, since only one signal duration was used, it cannot be determined from this study whether it was the absolute shock-free period or the ratio of the shock period (signal present) to the shock-free period (signal absent under the signaled condition) that controlled choosing the signaled condition.

The question of whether preference for the signaled condition is controlled by stimuli identifying the shock period (signal) or the shock-free period (signal absence) is important empirically and theoretically. One way of evaluating the role that these stimuli assume is by varying their dependability. In a study by Badia, Harsh, Coker, and Abbott (1976), the dependability of the signal in identifying a shock period was varied by

holding the total number of signals constant at 180 and varying parametrically the number of shocks from 180 to 3. Under these conditions, the probability of shock in the event of a signal varied, that is, p (US|CS) $\neq 1.0$, but the probability of shock in the absence of the signal always remained constant, that is, p (US|$\overline{\text{CS}}$) = 0. Badia et al. found that subjects changed to the signaled condition when the value of p (US|CS) = 1.0 and also when the probability was systematically reduced to less than 1.0. Apparently, the dependability of the signal that identified a shock period was not important as long as the probability of safety was not degraded, that is, as long as p (US|$\overline{\text{CS}}$) remained at 0. A variety of additional conditions, including controls for the intershock interval and sensory stimulation, were run.

In the second experiment, Badia et al. (1976) degraded the dependability of the stimulus identifying the shock-free period (safety), that is, p (US|$\overline{\text{CS}}$) $\neq 0$, while keeping constant the dependability of the stimulus identifying the shock period, that is, p (US|CS) = 1.0. The results showed that as the dependability of safety varied, preference for the signal condition also varied. When safety was dependably identified, preference for the signaled condition was strong, but when safety was undependably identified, preference for the signaled condition weakened. These results suggest that stimuli identifying shock-free periods are more important than stimuli identifying shock periods. The results also raise some interesting questions concerning the relative value of safety. Since subjects chose the signaled condition when safety was a nonzero value, that is, p (US|$\overline{\text{CS}}$) $\neq 0$, it is obvious that safety need not be absolute. Results similar to those of Badia et al. have been reported by Safarjan and D'Amato (1978). These investigators also concluded that preference for the signal condition was strongly related to the safety function of signal absence but not to the warning function of signal presence.

We have already noted the importance of signal duration in the early studies of preference (Perkins et al., 1966). Similar findings were reported by French, Palestino, and Leeb (1972). These early findings have been confirmed and supplemented by other research (Abbott & Badia, in press) using short signal durations with a different procedure and in a different apparatus. It was found that subjects generally did not prefer the signaled condition when the signal duration was less than 1 sec. Signal durations of 1.5 sec or longer, however, resulted in a strong preference. As noted, Perkins et al. found that preference was strongest with signal durations of 18 sec; French et al. found preference strongest with 30-sec durations. The theoretical implication of these findings is discussed later.

Other studies are relevant to an analysis of the factors affecting preference, and several investigators have assessed the attractive or aversive properties of stimuli that serve warning and safety functions (Arabian & Desiderato, 1975; Collier, 1977; Harsh & Badia, 1974). Harsh and Badia gave rats a choice between signaled and unsignaled shock while they were responding on a variable-interval food schedule. All the subjects chose the signaled condition, even though responding for food in the presence of the signal was suppressed. The rate of responding for food was lowest in the presence of the signal and highest in its absence. An intermediate rate of responding occurred under the unsignaled shock condition. Although it is clear that response suppression cannot always be used as an index of aversiveness (cf. Rachlin & Herrnstein, 1969), under these conditions we believe that the results suggest that the presence of the signal is the most aversive, that stimuli associated with the unsignaled condition are less aversive, and that the absence of the signal under the signaled condition is the least aversive.

The studies by Arabian and Desiderato (1975) and Collier (1977) assessed the characteristics of stimuli associated with shock periods (danger), stimuli associated with shock-free periods (safety), and signals preceding shock (warning stimuli). Three groups of rats were tested in each of the studies. One group was exposed to a situation in which stimuli identified shock and shock-free periods. In addition, during the shock periods

this group had a signal preceding each shock. Therefore, this group had stimuli identifying safe periods and danger periods, and also warning signals during the danger periods. A second group was essentially the same as the first, but instead of a signal preceding each shock during the shock periods, a random signal was used. For the second group, then, safe and danger periods were identified, but the warning signals were absent. The third group did not have stimuli that identified safe, danger, or warning periods. After training under the above conditions, the subjects were given a choice. Both studies reported that their subjects preferred the condition in which shock and shock-free periods were identified over the condition in which they were not. The subjects also preferred the condition of discriminable shock and shock-free periods when warning signals were added over the condition without discriminable shock and shock-free periods. Different findings were reported, however, when the subjects were given a choice between a condition in which stimuli identified shock and shock-free periods and one in which discriminable periods plus warning signals were present. Collier found that the subjects preferred the condition containing warning signals, whereas Arabian and Desiderato did not.

Conclusion

Our review of this portion of the literature dealing with the factors affecting choice permits a number of conclusions. The literature suggests that choice of the signaled condition does not occur at low levels of shock intensity. Generally, as shock intensity increases, so does choice of the signaled condition. The relation found between choice and shock intensity is similar to that found between performance and shock intensity in avoidable and escapable situations. The dependability of stimuli identifying a shock period appears to be relatively unimportant in terms of choice. Subjects chose the signaled condition even though the dependability varied markedly. On the other hand, the dependability of a stimulus identifying a shock-free or safe period is important. When this stimulus is made relatively undependable, choice of the signaled condition decreases. Long signal durations tend to be more effective than short signal durations. Signal durations of less than 1.5 sec generally do not result in a preference for signaled shock. Finally, very short (45 sec) or very long (120 min) intershock intervals attentuate preference for the signaled condition.

Failures to Replicate

Several studies have obtained preference for a signaled shock condition only when the shock was unscrambled (Biederman & Furedy, 1973, 1976a, 1976c; Furedy & Biederman, 1976). These data suggest that preferences for a signaled condition emerges only when subjects can overtly modify the shock through skeletal-muscular responses. This conclusion clearly disagrees with the findings reviewed earlier showing that subjects prefer a signaled condition with scrambled grid shock, with tail shock, and with water electrodes (e.g., Badia & Culbertson, 1972; Fisher & Badia, 1975; Miller et al., 1974).

Other studies by Biederman and Furedy (1973) have also failed to obtain a preference for signaled shock when it was scrambled. Yet, other investigators using a similar procedure have not had difficulty (Abbott & Badia, Note 2). Various possible reasons for the unusual findings of Furedy and Biederman are described in some detail in Badia and Harsh (1977a, 1977b). In part, they relate to the parameter values chosen by Furedy and Biederman, such as signal duration (3 sec), amount of training (none), length of testing phase (two 3-hour sessions), and intershock interval (45 sec). Some of these values have been shown to be less than optimal for demonstrating preference. In addition, the uncommonly long shocks used (5 sec) may have provided unusual opportunities for the unscrambled-shock subjects to learn competing responses.

We are aware of only one other study that failed to obtain a preference for a signaled shock condition over an unsignaled one (Crabtree & Kruger, 1975). In that study, however, several problems made finding a pref-

erence unlikely. The investigators used only one 13-hour testing session, an *n* of 1 in each cell for a 3 × 5 design, an intershock interval that was partially predictable, and a 3-hour pretest session with only the signal present. The latter procedure may have rendered the signal ineffective through the process of latent inhibition.

Related Findings

Studies using a choice as a dependent measure represent only one portion of a considerably larger amount of literature dealing with the role of predictability in aversive situations. This literature is much too extensive to be reviewed in any detail here; however, the general findings of studies involving measures other than choice are discussed insofar as they relate to the choice literature. (For a recent review dealing with response suppression under signaled and unsignaled conditions, see Hymowitz, 1979.)

Avoidance, Escape, and Punishment

The behavioral significance of signaling aversive events is clearly revealed in studies of avoidance, escape, and punishment. Sidman (1955) published one of the first studies comparing signaled and unsignaled avoidance schedules. Both shocks and signals were under the subject's control in this study. Responses in the presence of the signal postponed the next shock, and responses in its absence postponed both the signal and shock. The subjects allowed the signal to appear rather than postpone it, and overall avoidance responding dropped. Similar findings have been obtained by other investigators (e.g., Badia, Culbertson & Lewis, 1971; Hyman, 1969; Keehn, 1959; Ulrich, Holz, & Azrin, 1964). One explanation of the differences in responding may relate to differences in shock density under signaled and unsignaled schedules. Signals may allow a more effective avoidance strategy (i.e., result in fewer shocks). However, although some investigators have found shock density differences (e.g., Badia, Culbertson, & Lewis, 1971; Ulrich et al., 1964), others have not (e.g., Ayers, Benedict, Glackenmeyer, & Matthews, 1974; Logan & Boice, 1968; Powell, 1976). An explanation of the signaling effect based solely on an increase in response effectiveness is not supported.

Signaling also has a marked effect on behavior under schedules of escapable shock. Badia and Culbertson (1970) compared the behavior of rats under signaled and unsignaled escapable shock schedules and did not find differences in escape latencies. This outcome also suggests that behavioral differences resulting from signaled and unsignaled schedules are not due to response effectiveness. On the other hand, Badia and Culbertson did find clear differences in lever-holding time and in exploration. Holding was less frequent and exploration more frequent under the signaled condition.

Comparisons of signaled and unsignaled punishment schedules have yielded findings similar to those obtained with escape and avoidance (e.g., Church, 1969). Church found that immediate shock resulted in more suppression than did delayed shock. More interesting, however, a signaled punishment group showed less overall suppression than did an unsignaled punishment group, and the distribution of responding was different. Responding in the absence of the signal was higher than in the presence of the signal.

The studies reviewed thus far indicate that signaled and unsignaled avoidance, escape, and punishment procedures have different effects on behavior. When signals are present, they tend to gain control over behavior related to the postponement, termination, and/or prevention of shock. When signals are absent, the prevailing stimuli appear to set the occasion for behaviors not related to the control of shock (e.g., general activity, responding for reinforcement). When signals are unavailable, shock-related behaviors tend to predominate at all times.

Response-Independent Shock and Behavioral Suppression

In contrast to response-dependent shock (Church, 1969), other studies have assessed the effects of response-independent shock on behavior maintained by reinforcement, that is,

conditioned suppression (see Blackman, 1977; Davis, 1968). Some researchers have compared shock schedules with signals to shock schedules without signals (e.g., Brimer & Kamin, 1963; Davis & McIntire, 1969; Davis, Memmott, & Hurwitz, 1976; Holmes, Jackson, & Byrum, 1971; Seligman, 1968; Seligman & Meyer, 1970; Shimoff, Schoenfeld, & Snapper, 1969; Weiss & Strongman, 1969). These studies have shown that when shocks are signaled, the base rate of responding initially drops but gradually recovers over time. When shocks are not signaled, however, the base rate of responding drops to a low level and shows little recovery.

An example of correspondence between variables influencing choice and conditioned suppression concerns the dependability of predictors of shock and shock-free periods. In a study described in more detail earlier, Badia et al. (1976) reported that systematic reduction of the probability with which signals were followed by shock had little effect on preference, whereas degrading the dependability of a stimulus identifying a shock-free period had a marked effect. A similar finding using a conditioned suppression procedure was reported by Nageishi and Imada (1974). They studied the effects of varying the dependability of the shock-free periods on rats' licking behavior. They found that as the dependability decreased, the basal rate of licking also decreased.

Somatic Reactions to Shock

There has been a variety of studies comparing the somatic reactions to signaled and unsignaled shock, and many of the reports indicate that the effects of signaled situations are less severe than the effects of unsignaled ones (Gliner, 1972; Mezinskis, Gliner, & Shemberg, 1971; Price, 1972; Seligman, 1968; Seligman & Meyer, 1970; Simpson, Wilson, DiCara, Jarrett, & Carroll, 1975; Weiss, 1970, 1971a, 1971b, 1971c). The findings by Weiss (1970) are representative. Weiss found marked differences in the stress responses of subjects receiving signaled shocks and of subjects receiving unsignaled shocks. Subjects receiving unsignaled shocks developed more ulcers, lost more weight, and showed higher plasma corticosterone concentrations and higher body temperatures than did subjects receiving signaled shock.

The Weiss (1970) study and others clearly suggest that the somatic consequences of shock schedules are less severe when shocks are signaled. However, results involving somatic measures are not entirely consistent, and apparently contradictory findings have been obtained. Compared to unsignaled schedules, signaled schedules have been associated with heightened adrenal functioning (Bassett, Cairncross, & King, 1973; Paré, 1964), greater weight loss, and higher mortality rates (Brady, Thornton, & DeFisher, 1962; Friedman & Ader, 1965).

An explanation of the conflicting findings related to somatic reactions is not available. Weiss (1977) suggests that an examination of procedural variables reveals some consistencies. That is, somatic reactions to signaled schedules are less severe relative to reactions to unsignaled schedules when a direct-shock delivery system (e.g., tail shock) is used and are usually more severe when grid shock is used. Weiss (1977) related this pattern of findings to rats' coping behavior with different shock delivery systems. According to his view, the inefficient coping attempts associated with grid shock but not with direct shock may lead to more pathological changes. Not all findings are consistent with this notion however (Gliner, 1972; Seligman, 1968; Seligman & Meyer, 1970). It is apparent that additional data are needed to clarify this issue.

Theoretical Views

There are several ways of organizing the literature on predictability and behavior, particularly choice behavior. The findings could be organized along conditioned reinforcement lines. In its most simple form, this view states that neutral stimuli paired with primary reinforcers (e.g., food or shock) acquire reinforcing properties similar to those of the reinforcer. A conditioned reinforcement view can account for the findings obtained in experiments using food that subjects choose situations in which a signal precedes a posi-

tive reinforcer over situations in which no signal is given (e.g., Lutz & Perkins, 1960; Prokasy, 1956). To account for the preference for signaled over unsignaled food, it is assumed that the total amount of reinforcement is greater with the signal than without it, that is, the summation of the conditioned reinforcement occurring to the signal through pairings with food and the reinforcement of the food itself is greater than food reinforcement alone in the unsignaled condition. Generalizing this logic to the aversive situation, analogous reasoning would predict the opposite results, that is, shock plus the acquired aversiveness of the signal should be more aversive than the condition with unsignaled shock alone. As our view indicates, however, subjects under aversive stimulation clearly prefer signaled over unsignaled aversive situations. Obviously, conditioned-reinforcement theory alone cannot account for the literature showing that subjects prefer the signaled-shock condition. Nor can it account for appetitive findings showing that in some cases, subjects prefer unsignaled over signaled appetitive reinforcement (Hershiser & Trapold, 1971).

Another way of organizing the literature on predictability could follow an information-theory and uncertainty-reduction analysis (e.g., Berlyne, 1960). Berlyne's theory is based on the proposition that drive induces uncertainty and conflicts, and on the reinforcing effect of their reduction. All information is considered desirable, and the theory does not provide a basis for selecting information. Rather damaging to the uncertainty reduction view is the fact that it does not predict the findings of Defran (1972), Dinsmoor, Flint, Smith, and Viemeister (1969), Kendall (1973), and Wilton and Clements (1971). The Dinsmoor et al. and Defran studies are most illustrative. These investigators used an observing-response procedure and found that subjects would respond for stimuli identifying food periods (Dinsmoor et al.) or shock-free periods (Defran), but that they would not respond for stimuli identifying shock periods. Also, many investigators have shown that animals prefer information concerning reward over information concerning nonreward (Dinsmoor, Browne, & Lawrence, 1972), even when the information content is equal (e.g., Jenkins & Boakes, 1973; Peterson, Ackil, Frommer, & Hearst, 1972). Other findings difficult for the information–uncertainty-reduction hypothesis to address are those of studies showing that preference is a function of signal duration (e.g., Perkins et al., 1966), of reward magnitude (Mitchell, Perkins, & Perkins, 1965), or of stimulus dependability (Badia et al., 1976). It is apparent that the information hypothesis is not sufficiently developed to apply to much of the current literature, especially the literature on choice.

The two major analyses that have been applied to the choice literature are the preparation hypothesis and the safety hypothesis.

Preparatory Response Hypothesis

According to the preparation hypothesis (Perkins, 1955, 1968), stimuli that precede biologically important events allow subjects to prepare to receive these events. In turn, preparation is thought to minimize the painfulness of aversive stimulation or maximize the attractiveness of appetitive events. These preparatory responses are considered to be classically conditioned responses acquired through the law of effect.

The conditioned reinforcement hypothesis, and the preparation hypothesis predict similar outcomes in appetitive situations but not in aversive situations. Under aversive stimulation, the preparation hypothesis predicts that subjects will prefer signaled over unsignaled shock conditions. According to the earlier theorizing of Perkins (1955), signals preceding shock allow the subject to make preparatory responses (either internal or external) to shock, which reduces its aversiveness. In a later version of the theory, Perkins (1971) generalized preparatory responding to include the entire stimulus situation of shock and shock-free periods. This conception is in sharp contrast to the earlier view (Perkins, 1955), in which the emphasis was placed on specific responses. It is the earlier version of preparation that is most frequently tested and that is most testable.

Advantages of the preparation hypothesis.

One advantage of this view is its parsimony. The preparation hypothesis presents a one-factor view of conditioning in that both instrumental conditioning and classical conditioning are explained in terms of the law of effect. In addition, this view fits nicely with our intuitive notions of the kinds of behavior that should occur in response to signals that predict biologically important events. For example, given the opportunity, subjects should respond in ways that increase the attractiveness or decrease the aversiveness of environmental events. Numerous experiments dealing with escape and avoidance bear out this expectation. Preparatory responses clearly do occur under certain conditions. Another advantage of the preparation view is that it emphasizes the importance of such signal parameters as duration, variability, and dependability in determining choice. As noted, much of the evidence concerning choice under different signal conditions is consistent with preparation. It has been argued that in some situations longer signals allow more adequate preparation than do shorter signals, an outcome that has been found in several studies (Abbott & Badia, in press; French et al., 1972; Perkins et al., 1966). Particularly relevant are the findings of Abbott and Badia showing that signal durations of .5 or 1.0 sec would not support a preference for the signaled shock conditions. According to the preparation hypothesis, these short signal durations simply do not provide adequate preparation time. Signal variability could also be considered important for preparation. To be maximally effective, preparatory responses must be precisely timed, and conditions that allow this would be preferred to conditions that do not. Evidence supporting this view has been found by Safarjan and D'Amato (1977). This study reports that subjects prefer fixed over variable signal durations. The assumption of precisely timed preparatory responses also provides the rationale for predicting preference for immediate over delayed shock (e.g., Knapp et al., 1959).

The data on dependability of the signal reported by Badia et al. (1976) appear incompatible with a preparatory view. However, it may be possible to interpret the data of Badia et al. within a preparatory-response framework by (a) assuming a positive relation between preference and the proportion of shocks to which preparation occurred (Experiment 1) or (b) assuming preparation required little effort so that inappropriate preparation did not affect preference (Experiment 2).

Difficulties with the preparatory hypothesis. The preparatory view can account for a substantial portion of the literature on preference for predictable events. However, the strength of this view is also its weakness in that each successful account requires making a specific assumption about the nature of preparatory responses. Often these assumptions are deduced from the experimental outcomes that they allegedly predict. Since assumptions appropriate to any given outcome can be postulated, it is unlikely that a definitive test of the preparation hypothesis can be made. An important question, therefore, is whether the various assumptions made across experiments represent a unified view of the preparation hypothesis. Unfortunately, when the assumptions are viewed in this larger context, they often conflict. For example, to account for the choice of immediate over delayed shock conditions and of fixed over variable signal durations, it is assumed that preparatory responses must be precisely timed to coincide with shock (e.g., Knapp et al., 1959; Safarjan & D'Amato, 1977). Presumably, longer delays to shock make precise timing difficult. Yet to account for the stronger preference obtained with long over short signal durations, the opposite assumption is made, namely, that longer signals allow more effective preparation. Obviously, the precise timing and better preparation assumptions make opposite predictions in the same situation. The only criterion for choosing one assumption over the other appears to be the specific experimental outcome. A similar conflict of assumptions occurs when the rationale for choice is examined for studies involving the dependability of shock given the presence of a signal, or the dependability of no shock given the absence of a signal (Badia et al., 1976). In this case, it must be assumed that preparation is either effortful or effortless, or that there either is or is not a relation between preference and the pro-

portion of shocks to which preparation is made. In brief, when an internally consistent set of assumptions is adopted, coverage of the data is substantially restricted for the preparation hypothesis.

In addition to logical difficulties, there are also empirical difficulties for the preparation hypothesis (Badia, Coker, & Harsh, 1973; Badia, Culbertson, & Harsh, 1973). As noted earlier, subjects in the experiments of Badia and his colleagues chose signaled over unsignaled shock even though signaled shock was two to nine times longer, two to three times more intense, or four to eight times more dense. It seems unlikely that preparation would have reduced the aversiveness of signaled shock to that of unsignaled shock under all of these conditions. It is difficult to imagine a preparatory response so effective as to lower the aversiveness of the longer, stronger, or more dense signaled shock below that of the shorter, weaker, or less dense unsignaled shock. The results of the Harsh and Badia (1975) study showing that preference for the signaled condition increases as shock intensity increases are also difficult to reconcile with the preparation hypothesis. Presumably, preparation should occur at all intensity values. Other data argue against the preparation hypothesis as it relates to specific skeletal responses. The results of Miller et al. (1974), of Fisher and Badia (1975), and of others using surface electrodes to deliver shock rule out skeletal preparation that would have resulted in the subjects receiving different amounts of shock. Similarly, the study by Badia and Abbott (in press) monitoring shock duration found no differences between signaled and unsignaled conditions.

Some investigators have measured the response to an aversive event presented alone or preceded by a signal. Furedy and Doob (1972) summarized a number of experiments involving 150 human subjects and concluded that signaled shock failed to be rated less aversive than unsignaled shock. Similar results were also reported by Furedy and Ginsburg (1973) and Furedy and Klajner (1972).

An important series of studies reported by Gormezano and Coleman (1973) also relates directly to the question of preparation. Contrary to the preparation view, their findings suggest that the principle of reinforcement does not apply to classical conditioning. Gormezano and Coleman varied the effectiveness of preparation by attenuating the intensity of the US on trials in which a conditioned response was elicited. According to the preparation view, the frequency of conditioned responses should have increased; instead, this manipulation resulted either in no change or in a reduction in the frequency of conditioned responses.

Although a substantial literature indicates that a signal preceding shock attenuates an animal's distress vocalizations to that shock (e.g., Badia, Culbertson, Defran, & Lewis, 1971), the attenuation occurs the first time that the signal and shock are paired. Finding differences such as these on the first trial suggests that nonassociative factors are involved. Therefore the findings of Badia et al. cannot be used to support the preparation hypothesis. There are also studies with human subjects showing that the galvanic skin response to shock is smaller when shock is signaled (e.g., Baxter, 1966; Kimmel, 1967). This diminution in the galvanic skin response has also been found in the rat and has been interpreted as "preception" by Lykken (1962). Again, however, Badia and Defran (1970) have shown that the larger galvanic skin responses occurring to unsignaled shock resulted from orienting responses (Sokolov, 1963) occurring to the omission of the signal.

Safety Hypothesis

The first version of the safety hypothesis was offered by Mowrer (1960) to account for rats choosing signaled over unsignaled avoidable or escapable shock. Subsequently, the hypothesis was also used by Lockard (1963) and Seligman (1968). Seligman, Maier, and Solomon (1971) were the first to describe the analysis as the safety hypothesis, and they were primarily responsible for its development. Badia, Culbertson, and Lewis (1971) began to systematically apply the hypothesis to a wide range of preference findings, and the safety hypothesis soon challenged the preparation hypothesis as an interpretive model of preference in aversive situations.

The safety hypothesis emphasizes that situations with aversive stimuli can be divided into discriminably different components that vary in their degree of aversiveness. In its most simple form, emphasis is placed on discriminable shock and shock-free periods, whether shock stimulation is avoidable, escapable, or inescapable. These discriminable periods are orthogonal. For example, when subjects are given a choice between signaled and unsignaled shock, three distinct stimulus conditions exist: (a) the presence of the signal (CS) in the signaled condition, (b) the absence of the signal ($\overline{\mathrm{CS}}$) in the signaled condition, and (c) the unsignaled condition. Although the same shock distribution is used for both shock conditions and overall shock rates are identical, local shock rates may vary. In the signaled condition, shock always occurs in the presence of the signal, $p\ (\mathrm{US}|\mathrm{CS}) = 1.0$, and never in the absence of the signal, $p\ (\mathrm{US}|\overline{\mathrm{CS}}) = 0$. Under the signaled condition, therefore, shock (unsafe) periods and shock-free (safe) periods are perfectly identified, even when shock is randomly programmed. In contrast to the signaled condition, neither safe nor unsafe periods can be identified in the unsignaled condition, and with random shock, the entire intershock interval may acquire properties of an unsafe period. Thus, when subjects are in the signaled condition, the shock period is identifiable and usually brief—at most lasting only as long as the signal duration. Further, the safe period is also identifiable and considerably longer, since it consists of the total intershock times minus the signal duration. Presumably, subjects choose the signaled shock condition over the unsignaled one on this basis; that is, the safe periods are identifiable and are considerably longer than the unsafe periods.

Advantages of the safety hypothesis. One advantage of the safety analysis is that it can reconcile such findings as the acquired aversiveness of preshock stimuli with the findings that subjects prefer situations that include these stimuli. The safety hypothesis permits the generalization that stimuli paired with a reinforcer, positive or negative, acquire the properties of that reinforcer. Findings dealing with conditioned fear (e.g., McAllister & McAllister, 1971), with conditioned suppression (e.g., see review by Davis, 1968), and with inhibition and facilitation of avoidance (e.g., Rescorla & LoLordo, 1965) are compatible with this view. Support for the safety analysis can also be inferred from studies showing that greater physiological deterioration usually occurs when shock is unpredictable. Other data also support the safety analysis.

If safety is important, then its duration should be a factor. Stimuli associated with increased durations of shock-free time should acquire differential control over responses that produce these durations. The latter point is important because it demonstrates that factors other than the parameters of the aversive stimulus are controlling behavior. An example of one such effect involves the intertrial interval in avoidance learning, a factor known to be important in avoidance learning (e.g., Weisman & Litner, 1969a, 1969b). A more compelling set of data has also been provided by these investigators (Weisman & Litner, 1971). They used a procedure introduced by Rescorla and LoLordo (1965) in which a stimulus paired with shock or a different stimulus paired with no shock was presented. They systematically varied the duration of the no-shock period across groups and then imposed the stimuli identifying shock and no-shock periods on an avoidance task. When the stimulus identifying safety was imposed on avoidance, responding decreased. More important, the greater the duration of safety during the initial training, the greater the decrement in avoidance responding during testing. Other studies have also shown the duration of the shock-free period to be important (e.g., Azrin, Hake, Holz, & Hutchinson, 1965). As described earlier, Harsh and Badia (1976) demonstrated that the longer the duration of the shock-free period, the stronger the preference for the signaled over the unsignaled condition.

The results of Badia, Culbertson, and Lewis (1971) and of Badia and Culbertson (1972) also support a safety analysis. These investigators analyzed the stimuli within a preference task that controlled choosing the signaled condition. They demonstrated through a series

of extinction trials that the stimulus that was correlated with the shock-free period controlled changing from the unsignaled to the signaled condition. They also demonstrated that the stimulus (signal) that was correlated with the shock period, to which preparation could be made, did not maintain changing to the signaled condition. Other data also support the safety analysis. Harsh and Badia (1975) found that preference for the signaled condition varied with the intensity of shock. In another study (Harsh & Badia, 1974), they found that although subjects preferred the signaled shock condition, responding for food was most suppressed in the presence of the signal and least suppressed in its absence.

Difficulties with the safety hypothesis. Several findings are difficult for the safety analysis to accommodate. One of these findings deals with signal duration. Abbott and Badia (in press) found that animals did not prefer the signaled condition with signal durations of .5 or 1.0 sec but that with longer durations they did. Signal durations of the shorter length are clearly discriminable, thus allowing shock and shock-free periods to be identified; yet animals did not change to the signaled condition. Also, the finding that longer rather than shorter signal durations resulted in stronger preference for the signaled condition is incompatible with safety (French et al., 1972; Perkins et al., 1966). The recent work of D'Amato and Safarjan (1979) is also relevant. These investigators found that rats preferred information about the duration of shock that they were to receive, even though this information was unrelated to shock and shock-free periods. However, Freeman and Badia (1975), in a study similar to D'Amato and Safarjan, found that information about shock intensity did not result in a preference. Other results indicate that safety is not a necessary condition for preference. In a study by Badia et al. (1976), the dependability of the stimuli identifying shock and shock-free periods was varied. Preference for the signaled condition was maintained even when a number of unpredictable shocks were delivered during the formerly shock-free (safe) period. Only when the dependability of safety was reduced to a relatively low level was the preference eliminated. It is difficult for the safety analysis to deal with these data because the shock-free period was only relatively safe, not totally safe, under this latter condition.

Clearly, evidence for and against both the preparation analysis and the safety analysis exists, and perhaps both views have their merits under specific experimental conditions. However, preference for signaled shock may be determined by a number of factors, and it may not be possible to incorporate all relevant data under a single principle.

Prospectus

Our review of the literature has firmly established the reliability of preference for predictable shock situations under a variety of situations. The review rules out explanations of the phenomenon based on methodological considerations, such as differential shock avoidance or shock attenuation. It also rules out theoretical explanations of preference based on conditioned reinforcement or on the inherent value of information. Evidence favoring the remaining theoretical views of preparation and safety has been noted. We have also noted evidence incompatible with each of these latter views. For preparation, assumptions about the properties of preparatory responses across various conditions often are in conflict when viewed together. In addition, preparation theory fails to adequately account for the evidence showing that signals acquire aversive properties. The preparation view also has difficulty accounting for the preference for stronger, longer, or more dense signaled shock, for the controlling influence of stimuli correlated with safe periods, and for the failure of explicitly reinforced preparatory responses to maintain or strengthen conditioned responses. Similarly, the safety hypothesis has difficulty accounting for preference when safety is not completely dependable and for the marked influence that signal duration has on preference. It is apparent that neither the preparation hypothesis nor the safety hypothesis alone is sufficient to account for the available data. Predictable and unpredictable shock situations are probably more complex than these relatively simple theories

suggest. There may be other factors within these situations that are important.

One factor that may be important is local reduction in shock frequency or probability. Gibbon (1972, 1977), Herrnstein and Hineline (1966), Hineline (1970), and others have shown that reduction in shock density, both overall and local, is sufficient to maintain operant responding. Reduction in shock density also maintains choice behavior (e.g., Badia, Coker, & Harsh, 1973). Our view of preference based on shock-density reduction suggests that subjects change to a signaled condition because doing so frequently transfers them from a relatively high-density shock condition (unsignaled condition) to a relatively low-density shock condition (signal-absent component of signaled schedule), even though overall shock density is the same for both conditions. This view is compatible with a safety analysis based on discriminable periods relatively free of shock. When stated in relative rather than absolute terms, the safety hypothesis can account for choice performance under different dependabilities of safety. It is obvious that relative safety and local reduction in shock density are simply different ways of referring to the same controlling variable.

A second factor that may be important is the role played by classical conditioning. Even though this factor is explicitly recognized by the preparation hypothesis, it is treated only as a manifestation of the law of effect. Classical conditioning may have implications for behavior and physiology that differ from those stated by the preparation hypothesis. For example, whereas the preparation view suggests that conditioning should have beneficial effects due to a reduction in the aversiveness of the shock, the physiological evidence suggests that predictability can be more debilitating under certain conditions and less so under other conditions (Brady et al., 1962). More attention needs to be given to the role of classical conditioning and its interaction with operant choice behavior.

A third factor that needs attention is contrast. The signaled schedule may be compared to a multiple schedule in which the two components are identified by the signal's presence or absence. When components offering different reinforcement parameters are present in alternation, contrast effects often become evident. Indeed, the reinforcing value of safe periods emerges only as such periods are contrasted with periods of danger. The literature on contrast is extensive, but it is not yet clear how contrast alters the value and the physiological effects of signaled schedules.

Whatever the eventual theory, it is evident that signaled shock schedules are more complex than previously thought. Classical conditioning, successive contrast effects, local reinforcement, in addition to other factors, may all affect preference in signaled shock situations. The solution to the puzzle is not yet at hand, but progress toward such a solution is clearly being made.

The Alpha Experience Revisited: Biofeedback in the Transformation of Psychological State

William B. Plotkin
State University of New York at Albany

Presented is a review of empirical research and conceptual perspectives on the development of unusual experiential states during electroencephalographic (EEG) alpha-biofeedback training. It is concluded that the occurrence of the "alpha experience" is relatively independent of the strength or density of EEG alpha activity, and that the transformation in experience during feedback training can be accounted for by eight categories of complexly interrelated factors: (a) sensory deprivation, (b) sustained alertness, (c) concentration/meditation, (d) introspective sensitization, (e) expectation, (f) perceived success at the feedback task, (g) attribution processes, and (h) individual differences. Conceptual and empirical implications for biofeedback and for the study of physiological–experiential relationships are discussed.

During electroencephalographic (EEG) alpha-feedback training, trainees are presented with immediate moment-to-moment information on the strength or density of their EEG alpha rhythms, which provides them the opportunity, in principle, to learn to increase, maintain, or decrease the strength of this brain rhythm. Of special significance is the observation by some researchers (Brown, 1970; Hardt & Kamiya, 1976a; Hart, 1968; Kamiya, 1968, 1969; Nowlis & Kamiya, 1970) that many persons report entering a quasi-meditational state of consciousness during alpha-enhancement feedback training. This state of consciousness, often called the "alpha experience," is usually identified as a pleasant, relaxed, and serene state, characterized by a loss of body and time awareness, an absence or diminution of thought, and a feeling of egolessness (Brown, 1970; Hart, 1968; Kamiya, 1968, 1969; Nideffer, 1973; Nowlis & Kamiya, 1970; Plotkin, 1976a, 1977; Plotkin & Cohen, 1976; Walsh, 1974).

Initially, researchers claimed that the alpha experience was intrinsically and directly associated with enhanced alpha levels, and that the alpha experience was, in fact, *caused* by enhanced alpha levels (hence, the name, alpha experience). Frequently cited in support of this view (in addition to the early alpha-biofeedback studies) was the observation that the EEGs of meditators often show increased alpha strength during meditation (Anand, Chhina, & Singh, 1961; Kasamatsu & Hirai, 1969; Wallace, 1970). The possibility of directly influencing experience through voluntary control of the electrical activity of the brain was a rather provocative notion. Indeed, the great popular interest in biofeedback may have been primarily generated by the idea that brain wave–feedback training had the potential for being a more efficacious method than the traditional meditative disciplines for effecting meditative states, or that at least it was a method better suited to the "modern, Western temperament."

More recently, however, considerable doubt has arisen that changes in a person's EEG alpha level have any direct or simple relationship to the achievement of the alpha experience. Several studies have failed to find a significant occurrence of alpha experiences during alpha-enhancement feedback, especially when the research participants were not led to expect such an experience (Beatty,

Requests for reprints should be sent to William B. Plotkin, who is now at the Klamath Mental Health Center, 3314 Vandenberg Road, Klamath Falls, Oregon 97601.

1972; Lynch, Paskewitz, & Orne, 1974; Orne & Paskewitz, 1974; Peper, 1971; Plotkin, 1976a; Plotkin & Cohen, 1976; Regestein, Pegram, Cook, & Bradley, 1974; Travis, Kondo, & Knott, 1975). Plotkin (1976a), for example, found that one of his groups of research participants, who did not know which brain waves were being studied and who were not told what kind of experiences to expect, described experiences that showed "no consistent similarities with the experiences that have been widely associated with high and low alpha states" (p. 89). Travis et al. summarized the experiential reports of 140 persons who participated in four studies that examined the alpha-enhancement phenomenon. They concluded that the alpha-enhancement task is not as overwhelmingly pleasant as had been suggested by Nowlis and Kamiya (1970) and by Brown (1970).

On the other hand, there are several studies that have replicated the finding of alpha experiences during alpha training. However, when the relationship between EEG alpha and experience has been examined, these studies have uniformly failed to find significant correlations between the degree of alpha enhancement and the intensity or likelihood of alpha experiences (Beatty, 1972; Lynch et al., 1974; Plotkin, 1977; Plotkin, Mazer, & Loewy, 1976; Sacks, Fenwick, Marks, Fenton, & Hebden, 1972). Lynch et al., for example, concluded that their research participants' "largely positive reactions to the feedback procedure were not the result of large increases in alpha activity and are certainly not likely to have been a function of alpha activity levels alone" (p. 409). Using more formalized correlation techniques, Plotkin et al. found no correlation between the degree of alpha enhancement and the likelihood of an alpha experience.

Even more damaging to the thesis that the alpha experience is the result of alpha enhancement is the recently uncovered fact that there is absolutely no published evidence that alpha training has ever resulted in an unequivocal case of true alpha enhancement (Johnson, 1977; Paskewitz, 1977; Plotkin, 1978). That is, alpha levels have never been shown to rise above prefeedback eyes-closed resting baseline levels. The subbaseline increases in alpha production that have often been reported during alpha training have been shown to be the result of the gradual dissipation or neutralization of alpha-inhibitory influences, which is a case of disinhibition or habituation, not enhancement (Lynch & Paskewitz, 1971; Paskewitz, 1977; Paskewitz, Lynch, Orne, & Costello, 1970; Plotkin, 1978; Plotkin, Note 1).

Cognizant of this problem, Hardt and Kamiya (1976a) have argued that the failure to find reliable and significant alpha enhancement is due to the use of "deficient methodologies," such as insufficient training time or a percentage-of-time measure of alpha rather than an amplitude-integration measure (Hardt & Kamiya, 1976b). However, Plotkin (1976b) has pointed out that most of these "suspect" studies used methodologies that were similar to, or nearly identical with, those of the original studies of alpha-feedback training—those by Brown (1970), Kamiya (1968, 1969), and Nowlis and Kamiya (1970). Moreover, a recent study (Plotkin, 1978) that employed the precise methodology recommended by Hardt and Kamiya (1976a), including almost 9 hours of total training time, found no evidence for the learned enhancement of alpha strength significantly above optimal eyes-closed baseline levels, although in some cases alpha-enhancement training did result in the *maintenance* of optimal alpha levels.

In summary, there is now solid support for the conclusion that alpha-enhancement training per se is neither necessary for, nor especially facilitative of, the achievement of the alpha experience. However, it is important to note that the phenomenological authenticity of the alpha experience is not being called into question here. The point is that alpha enhancement per se has not been instrumental in—or intrinsic to—the achievement of this experience. Although there is always the problem of bias and compliance in the report of experiential states, most alpha researchers have learned that there is simply no doubt that many of their trainees have experienced highly unusual, meaningful, and occasionally profound alterations in consciousness during feedback training. That this is so is perhaps

Table 1
Factors Involved in the Development of Unusual Experimental States During Electroencephalograph Alpha-Biofeedback Training

1. Sensory deprivation due to
   (a) The biofeedback setting
   (b) Alpha-feedback-augmented sensory limitation
2. Sustained alertness (during sensory deprivation)
3. Concentration/meditation
4. Introspective sensitization
5. Suggestion and expectation due to
   (a) Preexperimental expectancies
   (b) Implicit suggestion
   (c) Explicit suggestion
6. Perceived success at the feedback task
7. Dual attribution of responsibility inherent in biofeedback training
8. Individual differences

best demonstrated by the extraordinary eagerness of many alpha trainees to repeat the experience, to learn all they can about it, and to spend considerable sums of money to purchase or rent the equipment that is seen as necessary for the generation of the experience (Lawrence, 1972). A recent study (Plotkin, in press) that employed a strong demand for honesty on experiential reports also supports this view. The question at this point is not whether these experiential reports are dismissable as artifacts, but rather, given that the attainment of the alpha experience during alpha training is not related to any unusual change in EEG alpha, how then *do* we explain the occurrence of these experiences?

We now appear to be in a position to offer an adequate answer to this question. Over the past few years there has accumulated a substantial body of evidence that demonstrates that there are at least eight categories of complexly interrelated factors (variables) that account for the occurrence of alpha experiences and similar states during alpha-biofeedback training. Table 1 presents an outline of these eight categories. Note that alpha enhancement is not among them.

Besides elucidating the development of alpha experiences, a review and discussion of these eight variables will highlight and illustrate several of the subtle, albeit critical, difficulties inherent in the attempt to establish direct or intrinsic relations between physiological states or processes and experiential or behavioral phenomena. There are complex methodological problems involved in determining how a particular physiological state is related, if at all, to a particular psychological state or behavior, and in deciding whether biofeedback or other means of altering particular physiological activities are critical to—or incidental to—the observed changes in psychological state (Shapiro, 1977). An understanding of how unusual experiential states are generated in the biofeedback setting will also enhance our knowledge of biofeedback training in its larger context of social and therapeutic influence—as opposed to its narrower definition as a method of facilitating physiological self-control.

Implicit in the reconstruction I shall offer of the development of these experiences will be a rejection of the reductionist and mechanist position that holds that psychological states are simply the consequence of efficient causes such as physiological processes and reinforcement histories. Instead, I shall proceed from a contextual human-action perspective, which recognizes that psychological state is one parameter or strand in a complex behavioral process that includes cognitions, motivations, and social significances as other parameters, as well as physiological processes and learning histories (Ossorio, 1973, 1978; Sarbin, 1977).

Sensory Deprivation

One hypothesis with respect to the development of unusual experiential states during alpha training is that the alpha-feedback setting happens to be conducive to the development of sensory deprivation and the associated alterations in consciousness (Zubeck, 1969). There appear to be, in fact, two independent aspects of alpha-training procedures that facilitate sensory deprivation: the attributes of the general biofeedback setting and the effects of alpha-enhancement training per se.

The Biofeedback Setting

There are several ways in which the typical alpha-biofeedback setting resembles those that

are employed in sensory-deprivation experimentation. Trainees are usually asked to sit in a comfortable chair or to lie on a bed, which is typically situated in a small soundproof or sound-attenuated room with low lighting or none at all. In addition, trainees are commonly asked to keep their eyes closed, to relax, and not to move around once they have become comfortable, in order not to disturb the EEG electrodes, which are sensitive to electromyographic (EMG) artifacts. Moreover, the standard feedback signal is a monotonous tone, usually appearing over a headphone set, which the trainees are constantly monitoring in order to track their changing alpha levels. Given these aspects of the typical alpha-feedback setting, it is not surprising that trainees often report becoming relaxed, with a loss of body awareness and with the associated sensory-deprivation feelings of lightness, floating, flying, or losing awareness of the "external" environment. However, as with sensory deprivation, some persons may react to this setting by falling asleep or with boredom, and some with anxiety or panic. The reason these latter responses are relatively rare during alpha training involves other factors discussed later, especially Factors 2 and 5 (see Table 1).

There has been only one piece of research (Plotkin, 1978) that has explicitly tested the hypothesis that the occurrence of the alpha experience is related to the sensory-deprivation aspects of the feedback setting. In this study, I found that persons who engaged in 10 52-min sessions of eyes-closed alpha-enhancement training without intrasession rest periods rated their experiences to be significantly more enjoyable and intense than did persons who engaged in precisely the same training with 20-sec eyes-open (and lights-on) rest periods interspersed every 4 min. The only significant difference in alpha levels between the two groups was a greater mean amplitude, on Session 1 only, for the group that did have the rest periods. Nevertheless, persons in the no-rest (high sensory-deprivation) group reported experiencing less body weight, greater personal involvement, faster speed of time, greater happiness, more emotional activation, greater personal relevance, more thought, and a "higher" state of consciousness. Moreover, relative to what might be thought to be more common procedures, the procedure of interspersing rest periods does not decrease the occurrence of alpha experiences: most of the studies that have reported the occurrence of these experiences have employed similar interspersed rest periods (Brown, 1970; Kamiya, 1968, 1969; Nowlis & Kamiya, 1970; Plotkin, 1976a, 1977; Walsh, 1974).

Alpha-Feedback-Augmented Sensory Limitation

Peper (1971) has noted another way in which the alpha experience may be related to a sensory-deprivation state. The research of Mulholland, his associates, and others (Mulholland, 1968, 1972, 1973; Mulholland & Peper, 1971; Wertheim, 1974) has demonstrated that the absence of occipital EEG alpha blocking reflects the absence of cortical oculomotor processing (in essence, abundant alpha occurs when a person is awake and "not looking"). Several other research reports (Chatrian, Magnus, Petersen, & Lazarte, 1959; Galin & Ornstein, 1972; Jasper & Penfield, 1949; Klass & Bickford, 1957; Kreitman & Shaw, 1965; Morgan, MacDonald, & Hilgard, 1974; Schwartz, Davidson, & Pugash, 1976) have suggested that the occurrence of alpha blocking at cortical locations other than the occipital lobe is also due to neural processing at the cortical location in question, with the concomitant activation of the behavioral processes associated with that location. In short, abundant alpha is known to accompany (or to be a sign of) sensory, motor, or cognitive quiescence at the cortical level. Thus, the *maintenance* of one's optimal *occipital* alpha level (which *is* facilitated through alpha-enhancement training; Plotkin, 1978; Note 1) would be expected to be accompanied by an absence of visual control processes. Moreover, because of the dominance of vision in the human being, alpha maintenance in the occipital lobe alone would be expected to have a *generalized* sensory limitation effect; that is, we would expect that the easiest way for an awake human being to minimize oculomotor activity—and thereby optimize

occipital alpha levels—would be for him to focus his attention on cognitive activity, and thus away from *all* sensory modalities, inasmuch as oculomotor activity is a concomitant of all sensory orientations.

In summary, it appears that occipital alpha-enhancement training results, to some degree, in a self-imposed sensory-deprivation state. Such a state would be expected to be characterized by increased nonsensory activity or awareness. However, the particular nature of this wakeful nonsensory state (e.g., introspection, daydreaming, boredom, hallucination, and some forms of meditation or contemplation) will depend on factors other than EEG alpha. Plotkin (1976a) and Plotkin and Cohen (1976) have demonstrated that there is a wide range of experiences that occur during alpha-enhancement training when the trainees are not led to expect any particular experiences. However, all of them are instances of nonsensory—and in particular, nonvisual—states.

Sustained Alertness During Sensory Deprivation

The quality of the experiences that occur during sensory deprivation would be expected to be very much influenced by the concurrent degree of alertness or drowsiness. In considering the explicit and implicit demands for relaxation in conjunction with the physical attributes of the feedback setting, one would expect drowsiness to regularly accompany alpha-feedback training. This development would be a problem for the researcher who is interested in evoking the alpha experience, since it cannot be experienced if the trainee is asleep; the alpha experience is an alert (although relaxed) state.

It is fortunate, therefore, that alpha-enhancement training facilitates the maintenance of alert wakefulness by facilitating the maintenance of naturally occurring eyes-closed alpha amplitudes. This feature of alpha training stems from one of the oldest EEG findings: Alpha activity decreases in amplitude and frequency, and essentially disappears, as a person becomes drowsy and approaches sleep (Adrian & Mathews, 1934; Berger, 1930; Lindsley, 1960). Thus, in order to keep the feedback signal on, the alpha trainee must learn to stay alert under sensory-deprivation conditions, a nontrivial task at which most trainees are nevertheless able to succeed. However, any task that would facilitate alertness and be compatible with sensory deprivation would do as well as alpha training in this regard. Yet we should note that alpha training is especially well suited for this purpose because it can be an absorbing task despite the fact that it involves only monotonous sensory stimulation (which renders it compatible with sensory deprivation).

Relaxed alertness may also be facilitated in the biofeedback setting by an upright posture (as in the traditional meditation position), by high levels of motivation or expectancy (to be discussed later), and, of course, by normal amounts of prior sleep.

The role of alpha training in facilitating relaxed alertness may help to explain why research participants in a noncontingent-feedback or a no-feedback group might not be as likely to report alpha experiences as those in a contingent-feedback group: The noncontingent and no-feedback participants are more likely to drowse off. Thus, it is not the case that enhanced alpha *causes* the alpha experience, or even that *maintained* optimal alpha is uniquely, intrinsically, or directly associated with the alpha experience; rather, drowsiness or sleep (which is accompanied by reduced alpha levels) is *in*compatible with the alpha experience. Maintained optimal alpha per se is as closely associated with alert daydreaming, mind-wandering, and boredom as it is with meditative experiences. Therefore, although alpha training per se may contribute to the occurrence of the alpha experience, it is not especially facilitative of it. The other factors discussed above and those to be examined below have been shown to be much more critical and influential in effecting the experiential state.

Concentration/Meditation

In addition to its sensory-deprivation qualities, the alpha-training procedure has some other important similarities to many meditation exercises, for example, immobility and concentration on, or sustained attention to, a

monotonous stimulus. The alpha trainees' task is to keep the alpha tone on as long (and/ or as loud) as possible. To accomplish this, they must intently focus their attention on the feedback tone, its variation, and the relation between the tone and their behavior and experience. This prolonged concentration on the feedback tone is formally equivalent to the meditator's sustained attention to breathing, to a mantra, to chanting or prayer, to a mandala, or to any other invariant or regular form (i.e., meditation object). As Naranjo and Ornstein (1971) have pointed out, this form of meditation exercise, which they call concentrative meditation, eventually results in a temporary suspension of ordinary thought, which is a central feature of the meditative (and alpha) experience, also reported by Deikman (1963) in his study of experimental meditation.

However, since the significance of the feedback signal, in its role as a meditation object, derives from its monotony, neutrality, and simplicity and not from its EEG contingency, it follows that a noncontingent tone would serve as well, in this regard, as the alpha tone in facilitating the generation of the alpha experience.

Introspective Sensitization

Recently, in a highly intriguing study, Hunt and Chefurka (1976) demonstrated that short periods of simply paying direct attention to one's "immediate subjective experience" elicited "anomalous subjective reports" and "altered-state effects" (p. 867). By "immediate subjective experience," Hunt and Chefurka mean "the bare features of momentary awareness without any reference to the consensual world of objects, persons, and meanings" (p. 868)—the "stimulus qualities" of sensations devoid of their significance as observations of everyday objects. Research participants who were requested simply to pay attention in this fashion for 10 min, without any explicit suggestions as to what to expect, generally reported "visual anomalies, uncanny emotion, . . . cognitive disorientation, and . . . feelings of interpersonal detachment and loneliness" (p. 872). The authors state that such data "suggest that altered-state effects can be tapped in very short time periods in any situation involving lack of movement, isolation, and at least implicitly, some attention to subjective experience" (p. 869).

The alpha-training situation certainly includes all of the latter three features. As we have seen, isolation and lack of movement are components of the sensory-deprivation qualities of the biofeedback setting. In addition, nearly all alpha-training studies include, at the very least, the implication that the training will result in mild to profound changes in experiential state. These experiential changes, which include changes in body awareness, are often explicitly outlined for the research participant before the onset of training (as will be discussed later). Thus we can conclude that the simple act of paying direct attention to one's sensations *as* sensations, which is a feature of the alpha-training context, can be expected to result to some degree in unusual experiential reports, independent of explicit suggestion, the degree of alertness, EEG alpha amplitudes, the presence of tones, or EEG-tone contingencies. "Introspective sensitization," as Hunt and Chefurka (1976) have termed it, is as much a feature of the alpha-training setting as it is of sensory deprivation, meditation, and hypnosis. Erickson, Rossi, and Rossi (1976), for example, have pointed out that

> the essential identity between periods of introspection and trance was demonstrated by Erickson . . . when he found that groups of subjects asked to perform a task in introspection underwent behavioral and subjective experiences that were similar to those they had when they went through a classical hypnotic induction. (p. 196)

Hunt and Chefurka (1976) also found that the experimental protocols of the classical introspectionists (e.g., Titchener, 1912; James, 1950; and Spearman, 1923) "revealed subjective anomalies similar to those found in drug and meditational states" (p. 867).

Suggestion and Expectation

The most widely endorsed hypotheses advanced to explain why unusual experiential states occur during alpha training have evoked such social psychological factors as suggestion, expectation, and the demand characteristics of the experimental setting (Beatty,

1972; DeGood, Elkin, Lessin, & Valle, 1977; Lynch & Paskewitz, 1971; Lynch et al., 1974; Peper, 1971; Plotkin, 1976a, 1976b, 1977, 1978; Plotkin & Cohen, 1976; Plotkin et al., 1976; Valle & Levine, 1975; Walsh, 1974; Glaros, Note 2). The central phenomenon here, of course, is the research participants' expectations about what sort of experiential changes will take place during training. These expectations can come about through (a) pre-experimental knowledge of alpha waves and/or alpha training, (b) explicit suggestion from the experimenter or from confederates, or (c) implicit suggestion (i.e., other demand characteristics).

It is certainly not surprising that expectation would play an important role in the development of alpha experiences during alpha-feedback training. After all, it has long been known that expectation has a very powerful influence on the often unusual experiences associated with hypnosis, relaxation procedures, meditation, and psychoactive drugs, as well as on all sorts of more common experiences. In reference to alpha training, Lynch and Paskewitz (1971), for instance, have made the following observation:

> Subjective reports are frequently influenced by the experimental setting and the course of the experiment itself. It is certainly possible that some of the reports of Ss in the feedback situation are influenced by what Orne (1962) has called the "demand characteristics" of the situation, that is, Ss enter the experiment expecting to experience alterations in mood, expecting the session to be pleasant, perhaps a "high," or if they don't feel this way initially, the experimenter may reinforce such feelings, both in the pre-experimental interview and in the actual instructions given during the experiment. (p. 212)

Preexperimental Expectancies

There has been only one published study (DeGood et al., 1977) that has explicitly assessed the effect of preexperimental expectancies on experiential reports of alpha training. DeGood et al. gave each of their research participants two 30-min feedback sessions: an alpha-enhancement session and an alpha-suppression session. Half of the participants had indicated on a screening questionnaire that they had some knowledge of alpha training, whereas the other half were "unknowledgeable" persons. The postexperimental experiential questionnaires indicated that only the knowledgeable persons experienced different subjective states during the enhancement and suppression sessions, with their reports of enhancement training being significantly more like the alpha experience than their reports of suppression training were.

Implicit Suggestion

To my knowledge, the effects of implicit suggestion in the alpha-feedback setting have never been documented independently of preexperimental expectancy. For instance, when expectancies are operative, one would naturally expect that informing a subject that she or he is about to begin an "enhancement trial" would serve as an implicit suggestion that the alpha experience is about to occur. This view offers the most plausible interpretation of a recent study by Glaros (Note 2), in which participants in one of the groups recruited for an "alpha-wave experiment" were given noncontingent (tape-recorded) feedback during both "enhancement" and "suppression" trials. These persons reported significantly more alpha experiences during the "enhancement" trials even though there was no difference in EEG alpha density between these two conditions.

Implicit suggestion should also be contrasted with inadvertent or informal suggestion, which occurs when the suggestion is not a formal component of the experimental instructions. Presumably, inadvertent or informal suggestion was at play in the early alpha studies, in which it appeared that there was a unique or intrinsic relation between alpha enhancement and the alpha experience (Brown, 1970; Kamiya, 1969; Nowlis & Kamiya, 1970).

Explicit Suggestion

The effects of explicit suggestion on reported experiences during alpha training have been an informal or secondary focus of several studies (e.g., Beatty, 1972; Lynch et al., 1974; Plotkin, 1976a). Beatty compared the experiential reports of participants in two contingent-feedback groups, one of which received no information about the alpha ex-

perience, while the other was informed of the phenomenological attributes of the experience. He reported a lack of uniformity in the reports of the no-information group. However, "subjects in the Information Condition, presumably because of their initial biases, reported the typical correlates of brain alpha rhythms—relaxation, calmness, inner awareness, etc." (p. 154). Lynch et al. reported that most of their subjects had positive reactions to the feedback procedures, but that "the most likely explanation for these positive reports rests in the fact that Ss were told that the experience would be a pleasant one" (p. 409).

There are three published studies that have systematically investigated the effects of explicit suggestion concerning the nature of the alpha experience (Plotkin, 1977; Plotkin et al., 1976; Walsh, 1974). Walsh employed a bidirectional design in which half of his research participants received alpha-suppression feedback and half received alpha-enhancement feedback. In addition, half of the persons in each of these groups received a "positive" alpha-experience set (explicit suggestion as to the nature of the experience), and half received a neutral set (general description of several possible experiences). Each research participant then received two 20-min sessions of alpha training, one with eyes open and one with eyes closed. Walsh found the typical alpha experience to be reported only when persons were given both the alpha-experience set and alpha-enhancement feedback. Either alone was not sufficient. Walsh interpreted these results as not only demonstrating the importance of suggestion, but also showing that the alpha experience is directly associated with the alpha rhythm, though this association may be blocked by "situational factors" unless the person is provided with "appropriate preparation for the experience, including some concepts to use in describing it" (p. 433). This latter conclusion, however, is not warranted by Walsh's data, since there is the following alternative interpretation, which has considerable independent support. Rather than demonstrating that the alpha experience is directly associated with alpha activity, Walsh's study may have shown only that the relative *absence* of alpha activity (during alpha-suppression feedback) is partially or wholly *incompatible* with the alpha experience (as well as with numerous other sorts of experiences associated with an inhibition of alpha blocking). According to this interpretation, the absence of alpha experiences in the groups that received alpha-suppression feedback (regardless of whether or not they also received the alpha-experience set) would be explained by this incompatibility rather than by a special, direct, or one-to-one relation between the alpha rhythm and the alpha experience. The finding of significantly more alpha experiences in the alpha-enhancement group that also received the alpha-experience set can be straightforwardly interpreted as demonstrating the effects of suggestion. Plotkin (1976a, 1977) and Plotkin and Cohen (1976) present data that demonstrate that alpha suppression, through its association with oculomotor activation, is antagonistic to the occurrence of the alpha experience.

In a related study, Plotkin et al. (1976) attempted to demonstrate the effects of suggestion on the experience of alpha training. Before the start of the 30-min eyes-open alpha-enhancement training, one group received an alpha-experience set; these research participants were explicitly informed about the specific experiential changes that were associated with increases in the volume of the feedback tone. The other group received no explicit suggestions whatever regarding what sort of experiences, if any, to expect. (Note that this no-set group differs from Walsh's neutral-set group. The latter was informed of a wide range of possible experiences, which included but did not emphasize the alpha experience.) No mention was made to any participant in either group that the research had anything to do with alpha waves (in order not to evoke preexperimental expectations). After the session, written experiential reports were collected and rated by blind judges on their similarity to a standardized description of the alpha experience. Somewhat surprisingly, the results showed that the likelihood of an alpha experience was not significantly different for the two

groups. However, this finding later came into focus when it was discovered that many of the research participants had spontaneously noted, on their postexperimental questionnaires, that they had felt very frustrated in their attempts to increase the tone volume (i.e., to enhance alpha). Thus, the alpha-experience set may have been ineffective at evoking alpha experiences because (a) the experience of frustration was incompatible with the alpha experience and (b) many trainees saw themselves as having failed at the very task that leads, they were told, to the alpha experience. This interpretation, then, suggests that the degree of *perceived* success at the feedback task should interact strongly with expectation. This hypothesis was tested in the following study.

Perceived Success at the Feedback Task

After the Plotkin et al. (1976) study, I was interested in demonstrating two separate points: (a) that the intensity of experiences reported to occur during alpha training would depend on perceived success at the enhancement task and be independent of actual success (the actual alpha amplitude relative to baseline) and (b) that the specific quality of the experiences would depend on the explicit suggestions given to the participants, assuming that preexperimental expectations were minimized. These two hypotheses were incorporated into a single 2 × 2 factorial design, in which the two between-group variables were Perceived Success (high or low) and Expectation (of one of two different sorts of altered states of consciousness). All participants received four 30-min. sessions of eyes-closed alpha-enhancement training, although it was insured that no participant thought that he or she was participating in research that was at all concerned with alpha waves. Persons who were randomly assigned to the lambda-expectation group were led to believe that they were training to enhance their "lambda" brainwaves, whereas the participants in the kappa-expectation group were told they were going to learn "kappa" enhancement. Both groups were told that they would find themselves in an altered state of consciousness (the "lambda" or "kappa" state, depending on the group) if they were successful at lambda (or kappa) enhancement. To determine the power of the Expectation variable, the lambda and kappa states were described as maximally dissimilar within the constraints of the biofeedback setting and the necessity of matching the motivational levels of the two groups. For instance, because of the sensory-deprivation qualities of the feedback setting, both groups were informed that the experience involved a loss of body awareness. Also, to insure an equal motivation to succeed, both states were described as pleasant, relaxing, and highly unusual and special. On the other hand, the two states were defined at opposite poles with respect to the more definitive aspects of the alpha experience: (a) the deliberateness and speed of thought, (b) the degree of "ego awareness," (c) emotionality, and (d) awareness of time. The lambda state (which corresponds to the alpha experience) was situated at the low end of each of these four dimensions, and the kappa state, at the high end. The major distinctive features of the lambda state were described as follows in the protocols:

> The "mind" slows down considerably during the lambda experience until the point is reached at which there is absolutely no thought, a condition often described as "blank mind." Even in the lighter stages . . . thought is very slow and free-flowing. . . . Eventually, thought stops entirely. However, the mind is nevertheless alert and awake at all times. . . . It is a clear and serene state—beyond emotion. . . . It is an "egoless" state, characterized by little or no awareness of oneself as a separate entity.

In contrast, the kappa state was described in the following manner:

> The "mind" becomes much more efficient in a certain sense. That is, the kappa experience is a state of very abundant and highly deliberate thought; we are able to direct our thought to any topic of interest and to process information at an extremely rapid rate. . . . It is characterized by abundant personal thought of a significant and often insightful nature. The kappa experience often involves thoughts of interpersonal experiences that are emotionally relevant . . . you become very aware of your personal strengths and of precisely who you are as a person.

Although all the research participants received the same form of contingent alpha feedback, half of those in each of the above groups—the "success" subjects—were made

to feel highly successful at the feedback task (regardless of the actual degree of success) by reporting to them (every 2 min via an intercom) a three-digit number that was ostensibly proportional to the preceeding trial's average alpha ("lambda" or "kappa") amplitude but was, in fact, the actual score inflated at a rate of an additional 2% every 2 min. Thus, while these "success scores" were still responsive to actual alpha amplitudes, and while the actual feedback tones were still being used, these trainees were nevertheless led to believe that they were improving at a somewhat remarkable, yet convincing, rate. In addition, persons in the Success group were given frequent verbal praise. On the other hand, persons in the "Failure" groups were given their actual 2-min scores, although their instructions informed them that the kappa (or lambda) experience does not even begin to occur until kappa (or lambda) strength is increased by at least 100% over initial levels (which never happens).

The fact that all participants were given contingent feedback is noteworthy. As many researchers have informally noted in their own labs, and as Strayer, Scott, and Bakan (1973) have formally demonstrated, many persons receiving noncontingent alpha feedback quickly grow discouraged, and often become drowsy or fall asleep. For this reason, noncontingent feedback (e.g., tape-recorded tones of a successful trainee) would not be effective for the Success group (they would not be as likely to feel successful) or for the Failure group (because, if they became drowsy, they would then manifest lower alpha amplitudes than the Success group, in which case perceived success would be confounded with actual success). In the experiment under consideration, then, the Failure subjects were able to feel that they had at least some control over the tone (which they did, in fact, have), although they were not able to produce the degree of enhancement that they believed was required to experience the alteration in consciousness. At any rate, it is because of the danger of the noncontingency being recognized that a noncontingent-feedback group is often not an adequate control group (Plotkin, Note 1).

The results from this study were straightforward. In general, and with few exceptions, in the written postexperimental questionnaires persons in the Kappa–Success group reported very powerful and genuine kappa experiences, while persons in the Lambda–Success group reported authentic lambda experiences. Most persons in both of the Failure groups reported "nothing unusual." These differences were borne out by statistical comparisons of the participants' ratings of their experiences on a series of 1-to-9 scales (Plotkin, 1977). As for the EEGs, there were no differences even approaching statistical significance between any of these groups in the degree of alpha enhancement actually achieved.

These results demonstrated (a) that the general intensity, pleasantness, value, and the degree of relaxation and sensory-deprivation effects that are reported to occur during alpha training are, indeed, very strongly influenced by the degree of perceived success at the feedback task; (b) that there is a wide range of experiences compatible with the biofeedback setting and abundant alpha activity—the "alpha experience" does not have a unique relationship to EEG alpha; (c) that the specific qualities of the reported experiences are closely related to the participants' expectations; and (d) that the quality and intensity of the experiences that occur during alpha training are independent of the actual degree of success at alpha enhancement.

The Attribution Process in Alpha Training

It has been established that alpha training per se is of little importance in the generation of experiential changes during these procedures. Nevertheless, it may be the case that the alpha experience is more likely to occur when the research participant can *attribute* the experience to alpha training or to another biofeedback procedure. For instance, would we find—or expect to find—equally profound changes in consciousness if we simply placed a person in a dark room for an hour and told him to expect—or to produce—certain experiential changes? What is it about the fact

that alpha trainees have this specific attribution available to explain to themselves the occurrence of these unusual experiences (namely, that they are the result of alpha training) that might enhance the likelihood of such experiences occurring in the first place?

An initial answer would be that alpha training serves essentially the same role as an inactive drug placebo: Just as there are many persons who will experience a suggested psychological effect after ingesting a purportedly psychoactive drug that is in fact only a sugar pill, there are many biofeedback trainees who will experience a suggested psychological effect during purportedly psychoactive biofeedback training that in fact has no significant physiological effect. (See Peek, 1977, for a discerning conceptualization of the placebo effect.)

However, the expectancy effect that is realizable in the biofeedback setting may be more powerful, or may at least have more active dimensions, than the typical drug placebo. There is one particular difference between a biofeedback treatment and a drug placebo that perhaps constitutes the most notable contribution of the entire biofeedback approach to therapeutic intervention: namely, the opportunity for the client, patient, or research participant to become an active agent in the process of change, control, or therapy (Stroebel & Glueck, 1973; Plotkin, Note 3). Whereas the recipients of a drug placebo are led to attribute the physiological, behavioral, or psychological transformation entirely to the drug (and thereby to reduce their own sense of responsibility and self-control), biofeedback trainees (whether or not the training per se has a humanly significant effect) will attribute a desirable outcome at least partially to themselves, which will *enhance* their sense of responsibility and self-control. In addition, there is, of course, a much greater likelihood of individuals eventually achieving complete self-control (without the aid of drugs or biofeedback) when they start from a point of *some* perceived control and move to one of more control, than when they attempt to go from no control to some control (Davison & Valins, 1969). In short, unlike placebo-treated persons, biofeedback trainees have been prepared to see themselves as least eligible for self-control of their problems, behavior, and/or experience (Plotkin, Note 3).

Thus, the biofeedback approach takes advantage of a combination of internal and external attributions of the suggested effect. There are two reasons why a biofeedback intervention may lead to a more powerful effect than an analogous external-placebo approach does. First is the fact that the experience of success at the feedback task may contribute directly to the outcome, especially when the major effect is an experiential or psychological change, as in the present case of alpha training. The self-control of an "involuntary" bodily process, especially one as mysterious and vital as brain wave activity, may be justifiable grounds for feelings of unusual self-mastery and for the accompanying positive affect. Furthermore, in the case of biofeedback there is nothing ambiguous about the occurrence of success: There is an objective measure of progress in the form of a feedback meter, tone, or other quantified index of control. Thus, the clinician or experimenter who employs biofeedback as a placebo intervention can arrange for his or her trainee to receive an indisputable feedback of "progress," which can serve as a very compelling counteragent to a trainee's lack of self-confidence and hence, as a powerful mobilizer of the trainee's motivations and skills.

The second advantage that the biofeedback intervention has over the external placebo follows from the fact that biofeedback trainees see themselves as active agents; they are therefore motivated to exert their own efforts toward producing the effect, an approach that may be expected to be more successful than that of placebo-treated persons, who usually have no reason to actively "help along" the drug (Valins & Nisbett, 1972). Alpha trainees would be expected to become more involved in—and thereby more influenced by—a procedure the effects of which they can see themselves as having facilitated than they would in a procedure that is ostensibly produced solely by an external agent.

Thus, Valins and Nisbett recommend that the individual who is treated with a drug or

placebo intervention be advised that the drug is "not so strong" and that it must be "helped along" by the appropriate self-control behaviors. When these procedures are used, the individual's self-doubts (about whether he or she can contribute to the production of the effect) are circumvented, and motivation and involvement are maintained. The biofeedback placebo goes even further in that the trainee's immediate task—control of the feedback signal—is at least one step removed from control of the target process or state (e.g., blood pressure, muscle group, or state of consciousness) and is thus less likely to evoke the trainee's doubts concerning his or her competence.

We would expect that alpha training would also be more effective than a procedure in which only *internal* attributions are available because most persons would probably not see themselves as able to induce such experiential states on their own without special training (for if they did, they would have done so already!). A person who starts out on a task that is believed to be impossible or doomed to failure is obviously less likely to succeed than one who thinks he or she has a good chance to succeed (Peek, 1977; Plotkin, Note 3).

These views concerning the attribution process in alpha training have received some support in a recently completed study (Plotkin, in press) in which experiential reports from six groups were compared. All the research participants were exposed to the identical physical setting and received the same explicit suggestions of an alpha experience. They were divided into the following 8 groups: (a) contingent EEG alpha-biofeedback training (participants in this group were instructed to try to increase the volume of a feedback tone; they were told that successful performance would enhance the strength of their alpha brain waves and thereby result in the alpha experience); (b) noncontingent biofeedback (instructions were identical to those above, but the "feedback" tone was in fact a tape recording of a successful trainee's feedback); (c) concentration exercise (an internal-attribution-only condition; the participants' task was to use the tape-recorded tone as a concentration object; successful concentration would lead to the alpha experience); (d) brain wave stimulation (the analog to the inactive-drug placebo; an external-attribution-only condition; the participants were informed that the alpha experience would be directly induced by a combination of electrical brain stimulation and computer-programmed auditory stimulation); (e) a combination of the last two groups (the participants were told that they were receiving direct brain wave stimulation, but that they must "help it along" by concentrating on the tone); and (f) self-induction (another internal-attribution-only condition, but unlike the concentration condition, participants were given no induction strategy; rather, they were on their own to self-induce the alpha experience in any way they could). The results from this study indicated that persons in the first two groups (biofeedback training) reported significantly more intense alpha experiences than did those in the other four groups. Moreover, there were no differences in experiential reports between the contingent and noncontingent versions of the biofeedback condition.

Individual Differences

Although the results of the Plotkin (1977) study demonstrated that reported experiences during alpha training were closely related to the participants' expectations and their degree of perceived success, there were nevertheless a few highly atypical responses in each group. A few persons in the Success groups reported no unusual experiences, or even the opposite experience to what they had been led to expect. In addition, a few persons in the Failure groups reported the suggested experiences despite our attempts to induce a perception of failure. These findings point to the importance of considering individual differences. Persons may have greater or lesser ability and/or disposition to self-induce unusual experiences or to self-induce one kind of experience over another. Moreover, persons differ in their proneness to experience sensory-deprivation effects, in their susceptibility or openness to suggestion, in their capacity to be comfortable in an experimental setting, in their disposition to follow instructions and

cooperate with the experimenter, and in many other relevant attributes. There has been very little work explicitly relating personal characteristics to the individual differences in reported experience during alpha training. A study in progress (Plotkin, Note 4) will correlate experimental reports with (a) state and trait anxiety (Spielberger, Gorsuch, & Lushene, 1970), (b) Rotter's (1966) Locus of Control Test, and (c) Shor's (1960) Personal Experience Questionnaire, which assesses the individual's proneness to naturally occurring altered-state experiences.

Related to the issue of individual differences is the study by Marshall and Bentler (1976), which demonstrated that alpha trainees who are deeply relaxed during training (as measured by forehead EMG) report significantly more alpha experiences than less relaxed trainees do, even when there are no differences in alpha density between the two groups.

Discussion

The research and concepts reviewed here appear to provide an adequate explanation of the development of unusual experiential states during alpha training. Of particular interest is the finding that there is no special, unique, or intrinsic relation between EEG alpha levels and the likelihood or intensity of the meditative state of consciousness known as the "alpha experience." Yet, at the same time, we can understand why it once appeared to researchers who were absorbed by the idea of a direct and simple relation between states of consciousness and neurophysiology that there was such an association: As it turns out, the alpha-feedback *situation* appears to be as effective as any other known procedure for generating such experiences in persons who do not have special meditation training. However, researchers were evidently unsuspecting of the strength and complexity of the eight non–EEG factors outlined in Table 1. Naturally, the early biofeedback investigators assumed that it was their operant-conditioning procedures, and not a conspiratorial set of "incidental" variables, that were responsible for their exciting results.

However, the research reviewed here does more than remind us that experiential states are complexly related to a host of parameters besides EEG alpha levels. It calls into question the entire enterprise of "mapping consciousness" neurophysiologically (Hilgard, 1969; Kamiya, 1968; Peper, 1972; Stoyva & Kamiya, 1968). As Grossberg (1972) has pointed out in reference to the present context of alpha-feedback studies, physiology and experience are of distinctly different logical types, so that not only is it unsurprising that we rarely find very tight relationships between them, it is also conceptually inappropriate to speak of any empirical correlations between them as a case of "mapping" if by this term we mean that the physiological states are formally equivalent to—or are efficient causes of—states of awareness, experiences, or behavior. What is called for at this point is not additional empirical specifications of physiology/experience or physiology/behavior correlations but rather an explicit and systematic articulation of the concepts of "persons" and "behavior," and of the logical relations between behavior, experience, psychological state, and physiological states (e.g., see Ossorio, 1973, 1978). Such an articulation will allow an understanding of the significance and implications of psychophysiological correlations that goes well beyond the simplistic and misleading notions of "mapping" or efficient cause.

There are several other implications of the findings reviewed here. First, although the research demonstrates that EEG alpha-biofeedback training per se is neither necessary for nor especially facilitative of the achievement of the alpha experience, the findings nevertheless add up to a very positive conclusion concerning self-regulation: The research demonstrates that we have greater abilities of self-control of experiential state than we have hitherto been willing to grant ourselves. As I concluded in an earlier article (Plotkin, 1976a),

> we should not be unduly disappointed that there is no direct association between enhanced alpha and the alpha experience. The chain of research on alpha feedback, from Kamiya's . . . first paper to the present, has been valuable in showing us that, although we once thought that a box of amplifiers and filters had made it possible to induce a de-

sirable state of consciousness more rapidly and effectively than ever before, in fact we were really always doing it "on our own." We simply discovered once again that often people only need a certain degree of faith in their natural powers and abilities, along with an appropriate setting and simple instructions, in order to accomplish what they feel is normally beyond their potential. . . . The power to enter altered states of consciousness is a *natural* ability that we all can potentially tap; learning how to do this without *external* devices such as electronics and drugs will serve to expand our behavior potential in the widest range of circumstances. (p. 97, italics in original)

Thus, it appears that Maslow (1969), for example, was somewhat mistaken when he concluded from the early alpha studies that "it is already possible to teach people how to feel happy and serene" (p. 728). It would now seem more appropriate to say—and, incidentally, this is more in keeping with humanistic themes—that we have discovered that it has always been possible for people to *allow themselves* to feel happy and serene.

A second related implication concerns the similarity between the alpha-feedback phenomenon and the hypnotic situation: Both are ways in which latent behavior potential can be evoked, and in a similar manner. One procedure for inducing the hypnotic state (Plotkin & Schwartz, Note 5) centers around the hypnotist's carefully timed redescriptions of behavior: The hypnotic subject's behavior is redescribed in such a way that the subject comes to see his or her own behavior as occurring "automatically" or under the "control" of the hypnotist. For example, the subject's arm may be seen as rising autonomously when the subject is, of course, the one who is actually raising it. Similarly, the biofeedback researcher gives an (unintentionally) inaccurate description of the alpha-feedback situation with the result that the trainee believes that the promised experiential state is a consequence of biofeedback-augmented alpha enhancement rather than the trainee's direct achievement (the latter being, in fact, the case). With this redescription of the trainees' behavior, the researcher has managed to circumvent the typical trainees' self-doubts about their abilities to put themselves in this state, which leaves them in a position in which they can simply go ahead and do just that (as long as they do not see it that way at the time). In essence, the trainees are supplied with a special description of the behavior whereby they self-induce a change in consciousness so that they do not fully recognize their behavior for what it is. Inasmuch as they think that their potential effectiveness is limited to controlling the feedback tone, they do not recognize the situation as one in which there is, in fact, a question about their ability to self-induce the alpha experience; or if they do recognize the situation, all the evidence is stacked against their self-doubts, since they are, after all, "objectively" succeeding at the task! In sum, although biofeedback researchers have not been fully aware of it, alpha-feedback training has been a situation in which biofeedback has been used as an element in a somewhat sophisticated social-influence process that can lead to the evocation of latent powers of self-control.

These conclusions should not be taken as a disparagement of biofeedback training; biofeedback does represent a valuable advance in our capacity to introduce ourselves to new realms of physiological and psychological self-control. Rather, this research suggests at least two cautions or reminders for biofeedback users and researchers. First, we must distinguish between the intrinsic and the instrumental uses of biofeedback training. Biofeedback is used for intrinsic purposes when the physiology that is being controlled, is being controlled for its own sake. For example, the use of biofeedback training for the reduction of high blood pressure or for muscular reeducation is an instance of intrinsic use: If the hypertensive can use the biofeedback monitor to learn to lower his blood pressure, or if the cerebral-palsy victim can employ the information supplied by an EMG monitor to learn to coordinate his movements once again, then there is no question that the physiological control itself is valuable. On the other hand, when biofeedback is used instrumentally, we cannot be as sure that the physiological control *per se* will be at all useful. Biofeedback is used instrumentally when the control of some aspect of our physiology is attempted not because this control is intrinsically valuable, but because it appears to

lead to—or to accompany—some other desirable state of affairs. For example, the use of EMG biofeedback training for anxiety reduction, or the use of EEG biofeedback training for "mind control," for altered-state induction, for pain control, or as psychotherapy for neurotics or alcoholics is an instrumental use. When biofeedback is used instrumentally there is a gap, usually a categorical gap, between the physiological process that is being self-regulated and the desired behavioral or psychological outcome. In such cases we must be most careful before concluding that the control of the physiology in question has any special relevance to the desired or attained goal.

The second reminder balances out the first: Biofeedback training is not merely a form of manipulation of human physiology; it is a complex social–behavioral interaction in which not merely physiology but attitudes, expectations, motivations, attention, experience, alertness, and understandings are being directly and indirectly influenced independently of any contingencies between physiology and feedback. The present article illustrates how biofeedback training can be more fully understood if it is viewed as a social-therapeutic activity with important physiological aspects, as opposed to being thought of as a strictly physiological training procedure with incidental (and perhaps annoying) social attributes. Especially when employed instrumentally, the general biofeedback framework is not merely a novel application of operant conditioning methodology but a potentially powerful context for the mobilization and activation of our latent self-control and self-healing capacities (Plotkin, Note 3). It is in this latter role that biofeedback training may find its most fruitful applications as a therapeutic tool.

Statistical Adjustments and Uncontrolled Studies

Herbert I. Weisberg
The Huron Institute, Cambridge, Massachusetts

Many evaluations of social interventions are based on uncontrolled assignments of individuals to treatment groups. Statistical adjustments are often used to compensate for naturally occurring differences between groups. There is much confusion and controversy about the adequacy of these statistical methods. A variety of interrelated problems have been identified, including measurement error, unequal growth rates across groups, and regression artifacts. In this article it is shown that these problems can all be subsumed under a general conceptual framework, as particular examples of model misspecification. This perspective is helpful in revealing clearly the nature of the problems posed by lack of experimental control. The important case of linear adjustment (analysis of covariance) is given special attention. An expression is derived for the proportion of bias remaining after adjustment, in terms of easily interpretable parameters. Implications of these results for research and evaluation design are considered.

To evaluate the effectiveness of a social intervention, the performance of a group receiving the "treatment" must be compared with a standard representing the expected performance in the absence of intervention. The fundamental problem in research design is to find a valid standard of comparison. Randomization is generally accepted as the ideal approach. That is, we use a random mechanism to assign individuals to either a treatment group or an untreated control group. Random selection virtually guarantees (at least for large samples) that the control group's performance will correspond to that of the treatment group without the intervention. So a straightforward comparison of mean outcomes for the two groups will provide an unbiased estimate of the treatment's effect.

Often, however, it is impossible to exercise experimental control. Complex social forces unknown to the investigator determine which individuals wind up in each of the groups. With such uncontrolled selection designs, the straightforward difference of group means may be a biased estimate of the effect. In these situations a variety of statistical methods have been proposed to compensate for this bias and thus provide an unbiased estimate. The analysis of covariance (ANCOVA) is perhaps most widely used for this purpose.

Recently there has been a great deal of concern about the adequacy of ANCOVA and other statistical adjustment procedures. Several investigators have shown that under models representing uncontrolled selection, the ANCOVA may either overadjust or underadjust (Bryk & Weisberg, 1977; Cain, 1975; Cochran & Rubin, 1973; Cronbach, Rogosa, Floden, & Price, Note 1). The estimates generated may in some instances be seriously misleading. It is even possible for the remaining bias after adjustment to be larger in absolute value than the initial bias without any adjustment.

Confusion over the adequacy of statistical adjustments is part of a larger debate about the usefulness of designs based on uncontrolled

studies. Some analysts (see Campbell & Boruch, 1975; Gilbert, Light, & Mosteller, 1975; Riecken & Boruch, 1974) argue forcefully that randomization is essential and often feasible. Yet the vast majority of social research is based on uncontrolled selection, because a wide variety of practical, ethical, and political problems prevent the implementation of rigorous randomized experiments (e.g., see Cohen, 1975; Suchman, 1967; Weiss, 1972). Thus it is crucially important to understand exactly what problems are associated with uncontrolled studies.

The present article proposes a conceptual framework that may help to clarify these issues. I shall begin with a discussion of statistical adjustment in general, and then consider in detail the important special case of linear models. The perspective is similar to that of several other investigators (Barnow & Cain, 1977; Cain, 1975; Cochran & Rubin, 1973; Cronbach et al., Note 1; Goldberger, Note 2), and some of the specific results can be found in their work. One of the main objectives of this review is to draw together insights scattered throughout the extensive literature on the adequacy of adjustments.

Statistical Adjustments for Confounding Variables

To avoid confusion, we will not consider the effects of finite sample sizes, or the accompanying problems of estimating parameters on the basis of data. Such issues compound the problems addressed here but do not affect the basic argument. In effect, we will be considering the case of large samples, so that the precision of estimated parameters is very high.

Let us consider the study sample as randomly drawn from some population. Individuals in the sample are assigned to a treatment or control group on the basis of a mechanism that may or may not be known. Following Rubin (1974), we can think of two potential outcomes corresponding to each individual: the outcome received under the treatment and that received without any intervention. We can define Y_i: observed outcome under treatment actually received, W_i: outcome that would have been observed under treatment, and Z_i: outcome that would have been observed under control conditions.

These definitions may at first seem confusing. To understand them clearly, it may be helpful for the reader to imagine a two-stage process consisting of group selection and treatment administration. In the first stage, individuals are assigned to the treatment and control groups as they would be at the beginning of a study. At the second stage, however, there are three alternative possibilities.

First, the study may be carried out as planned, with subjects who are assigned to the treatment group receiving the treatment and control subjects experiencing no intervention. In this case, the observed outcome corresponds to the variable Y defined above. The second possibility is to suspend the study and simply give the treatment to all subjects. The outcome in this case would be W. Finally, we can suspend the study but give the treatment to no one. Then the outcome would be Z.

Ideally, the effect of the treatment would be assessed by comparing W_i and Z_i for each individual i. But of course, in general, the second and third options described above are strictly hypothetical, and we will have information only on Y. The key question in uncontrolled studies is whether we can obtain a useful and valid estimate of effect when only Y is available. Under what circumstances will an actual study allow us to make inferences about what would have occurred under different scenarios?

A general answer to this question would be extremely complex. Note that for each individual the treatment effect is given by

$$\alpha_i = W_i - Z_i. \tag{1}$$

In general, α_i may depend on individual characteristics and even on the selection mechanism. For example, suppose we happen to assign to the treatment those who can benefit from it the most. Then the average effect for those in the treatment group will be relatively large. But the results will generalize only to similarly selected groups. When the α_is are related to individual characteristics in this way, caution is required in the interpretation of average effects.

Although this issue of interactive effects is an important and confusing one, I wish in this article to highlight the problems pertaining specifically to statistical adjustments. Let us

therefore restrict consideration to the situation in which the treatment effect is constant across individuals. That is,

$$W_i = Z_i + \alpha, \tag{2}$$

so that we can write

$$Y_i = Z_i + Q\alpha, \tag{3}$$

where $Q_i = 1$ if subject i is in the treatment group and $Q_i = 0$ if subject i is in the control group. Note that if Q is determined by a random mechanism, then each individual has the same probability of being assigned to the treatment group. Let P be the total proportion assigned to the treatment. Then

$$P(Q = 1) = P$$

and

$$P(Q = 0) = 1 - P. \tag{4}$$

Under randomization, the expected value of Z for those in each group should be identical. That is, if we define

$$\mu_{Z1} = E(Z|Q = 1)$$

and

$$\mu_{Z0} = E(Z|Q = 0), \tag{5}$$

we would have

$$\mu_{Z1} = \mu_{Z0}. \tag{6}$$

If, however, the assignment mechanism is nonrandom, it is possible that $\mu_{Z1} \neq \mu_{Z0}$. Even with no intervention, there might be a difference in mean outcomes between the groups. In this case, if we simply compare the mean observed outcomes for the groups, we will obtain on the average (and approximately for large sample sizes)

$$\mu_{Y1} - \mu_{Y0} = \alpha + \mu_{Z1} - \mu_{Z0}. \tag{7}$$

That is, the estimated effect will be inflated by $\mu_{Z1} - \mu_{Z0}$. While under randomization $\mu_{Z1} - \mu_{Z0}$ will be 0, under nonrandom assignment it may be either positive or negative. This term represents the *selection bias* in estimating α. Equations 5 and 7 show that the bias is determined by the relationship between Z and Q in the study sample. In fact, it will be convenient for us to reexpress this relationship, using the well-known formula for the point biserial correlation (e.g., see McNemar, 1969, p. 218) as:

$$\mu_{Z1} - \mu_{Z0} = \frac{\sigma_Z}{\sqrt{P(1-P)}}\rho_{ZQ}, \tag{8}$$

where σ_Z is the overall standard deviation of Z and ρ_{ZQ} is the correlation between Z and Q.

The dilemma posed by uncontrolled studies is that this correlation cannot be estimated empirically. Without the intervention, the distribution of Z could be obtained, but there would be no information on Q. After the study, Q can be observed, but Z is no longer observable. The observable outcome is then the modified variable Y that includes a component attributable to the treatment. From Equation 3 it is clear that the relationship between Y and Q is not the same as that between Z and Q. Thus the crucial relationship between Z and Q cannot be observed.

In many situations, however, it is possible to identify other variables that are related to the assignment variable Q, and which are thought to "explain" the relationship between Z and Q. That is, differences between μ_{Z1} and μ_{Z0} are caused (at least in part) by differences between groups in the distribution of these "confounding factors." If such factors can be identified and measured, it may be possible to compensate for their effects in estimating α. Statistical adjustments are based on this idea.

Intuitively, a confounding factor can be defined as a variable that has a different distribution in each of the treatment groups and that is causally related to the outcome variable. This definition is ambiguous, however, because the concept of causality is difficult to operationalize. Whatever we mean by causal influence, it seems likely that in general the value of $\mu_{Z1} - \mu_{Z0}$ will be determined by a complex combination of variables. The actual selection process, moreover, may be described in more than one way. We may have many equally plausible "explanations" for group differences. So it may be unrealistic to expect an unambiguous criterion defining a confounding factor.

On the other hand, it is not unreasonable to ask whether in a particular study, using statistical adjustment and a given set of adjustment variables (covariates), an unbiased estimate of α can be expected. Further, we can try to specify the general conditions under which adjustment will be useful. What properties must X have in order to eliminate bias completely, or at least reduce it to an acceptable level? Can we assess the amount of bias

remaining after adjustment? These questions will be addressed in the remainder of this article.

Complete Elimination of Bias

Let $E(Z|X)$ be the conditional expectation, or mean, of Z given X. It is the average value of Z in the study population for individuals having a given value of X. Thus it is in general a mathematical function of X.

Similarly, let $E(Z|X, 1)$ be the conditional expectation of Z given X for those individuals assigned to the treatment group. Let $E(Z|X, 0)$ be the conditional expectation for control group subjects. In general, these expectations will not be equal for a given value of X. Suppose, however, that

$$E(Z|X, 1) = E(Z|X, 0) \qquad (9)$$

or equivalently that

$$E(Z|X, Q) = E(Z|X). \qquad (10)$$

This means that even though the unconditional expectations for the two groups differ, the conditional means are equal. Conditioning on X eliminates the selection bias. We will say in this case that X is a *complete* confounding factor.

To see more clearly the importance of this condition, suppose we "match" two individuals on the basis of a variable X for which Equation 10 holds. Let Z_1 be the outcome for the treatment group subject and Z_0 be the outcome for the control group subject. Then

$$E(Z_1|X, 1) - E(Z_0|X, 0) = 0, \qquad (11)$$

so that

$$E(Y_1|X, 1) - E(Y_0|X, 0) = \alpha. \qquad (12)$$

By matching individuals on the basis of a complete confounding variable, we can obtain an unbiased estimate of α. Such matching procedures are commonly employed, particularly in medical research. There are of course many practical problems to deal with, even though the method is theoretically correct. Rubin (1973a, 1973b) provides an excellent discussion of these problems. A less technical but more comprehensive review is provided in Anderson et al. (in press).

Note that there may be many different complete confounding factors satisfying Equation 10. If they vary in terms of the strength of their relationship with Z, some factors will result in more precise estimates of α than others will. In terms of bias reduction, however, they are all equivalent. Note also that X may be a vector consisting of several variables. Equation 10 is still the defining property.

Now suppose that a "covariate" X (either univariate or multivariate) is used for adjustment, and Equation 10 does not hold. Then there may be differences between groups that are unrelated to X. So after adjustment for X, there may remain an apparent treatment effect really attributable to preexisting group differences.

The controversy over statistical adjustments mentioned above centers on the adequacy of the Xs used in practical applications. If adjustment proceeds as if Equation 10 holds, and a more general model of the form

$$E(Z|X, Q) = f(X, Q) \qquad (13)$$

actually holds, how well do these procedures perform?

Stated in this way, the adequacy of statistical adjustment may be seen as a problem of model specification. Essentially, we are estimating a parameter α under a particular restricted form of the relationship between Z, X, and Q. We wish to know how accurate our estimate will be if a more general model actually holds.

Note that from this perspective, the important issues concern the relationships among real, *potentially* observable variables. Although it is true that Z and Q cannot be observed together in the same study, each could be observed if we were willing to forego the other. The adequacy of adjustment depends on how the covariate X relates to these two variables.

It is perhaps worth contrasting this perspective with that adopted in the widely circulated paper by Cronbach and his Stanford colleagues (Cronbach et al., Note 1). These authors define a true model in terms of two ideal variables. The performance of adjustments is then assessed in terms of the relationship between the covariates actually used and these unknown, ideal factors. However, the ambiguity inherent in defining and interpreting these constructs and the complexity of the

mathematical analysis have led to some confusion. By avoiding hypothetical variables, I hope to provide a clearer understanding of the problems encountered in practical situations.

Note that while Equation 10 specifies a theoretical condition for complete adjustment, this condition is difficult to verify in practice. Generally speaking, we can be sure that the condition is fulfilled only when the investigator has complete control over the assignment of subjects to treatment groups. With complete control, the experimenter has two main options: randomization and explicit control.

When individuals can be assigned randomly to the two groups, $\mu_{Z1} - \mu_{Z0} = 0$, and statistical adjustment is unnecessary. If adjustment is performed using any covariate, the estimate of effect remains unbiased and may have greater precision. Increase of precision in randomized experiments was in fact the original purpose of the ANCOVA (Fisher, 1932).

By explicit control, we mean that a covariate X serves as the sole basis for group assignment. That is, the probability of being in each group can depend on X but no other variable. In practice, this amounts to conditional randomization, since for a given value of X, individuals are assigned randomly with the value of P a function of X. Rubin (1977) has recently advocated designs based on explicit control for educational research.

In the extreme case when the probability of assignment to the treatment group is either 0 or 1 for any given X value, we have deterministic assignment conditional on X. The special case when all individuals below a certain cutoff score on X are assigned to one group and those above to the other group has been called the *regression discontinuity design* (Campbell, 1969; Campbell & Stanley, 1966). The problem with this design is that, although X is indeed a complete confounding variable, the distribution of X in the two groups does not overlap. Thus we cannot match individuals on the basis of X, and we must rely heavily on model assumptions in order to analyze such experiments.

As mentioned above, both randomization and explicit control require that the investigator be able to determine the assignment procedure. In fact, these two techniques constitute the backbone of controlled experimentation in the Fisherian tradition, and a huge literature has developed to elaborate on these two basic ideas (e.g., Cochran & Cox, 1957; Cox, 1958; Kempthorne, 1952; Winer, 1971). This tradition relies on experimental control as the prerequisite for causal inferences.

In our terms, then, experimental control is the only general method of insuring that the covariates employed in a given study constitute complete confounding factors. With uncontrolled studies, we will not know how much bias remains after adjustment. Moreover, because there is an unlimited class of possible models relating Z, X, and Q, we cannot hope to answer this question definitively. Restricting consideration to linear models, however, will provide some helpful insight.

Linear Models and the Analysis of Covariance

Let us assume that

$$E(Z|X, Q) = \mu + \beta X + \delta Q. \qquad (14)$$

In this model δ can be interpreted as the expected difference in Z for individuals in the two groups with identical X values. Now if X is a complete covariate, then Equation 14 reduces to

$$E(Z|X, Q) = \mu + \beta X, \qquad (15)$$

so that

$$\mu_{Z1} - \mu_{Z0} = \beta(\mu_{X1} - \mu_{X0}), \qquad (16)$$

and we could form the estimator

$$\hat{\alpha} = \mu_{Y1} - \mu_{Y0} - \beta(\mu_{X1} - \mu_{X0}). \qquad (17)$$

From Equations 7 and 16, we see that $\hat{\alpha}$ will be an unbiased estimator of α.

If we ignore finite-sample estimation problems, Equation 17 represents the ANCOVA estimate of α. Now suppose that an ANCOVA is employed when the true underlying model is given by Equation 14. Note first that δ represents the bias remaining after adjustment by ANCOVA with X as the covariate. We will be interested in the relationship between δ and the initial bias without adjustment $(\mu_{Z1} - \mu_{Z0})$. The ratio of these quantities may be termed the proportion of initial bias remaining, which we will denote π. We use the term proportion

in a general sense, since π need not necessarily lie between 0 and 1.

Note that from Equations 3 and 14 we have

$$E(Y|X, Q) = \mu + \beta X + (\delta + \alpha)Q. \quad (18)$$

So α and δ are totally confounded in terms of the linear model relating observable variables. Thus instead of estimating α as we could if X were complete, we can only estimate $\delta + \alpha$.

Let us denote the matrix of correlations among Z, X, and Q by

$$\begin{bmatrix} 1 & \rho_{ZX} & \rho_{ZQ} \\ \rho_{ZX} & 1 & \rho_{XQ} \\ \rho_{ZQ} & \rho_{XQ} & 1 \end{bmatrix}.$$

Consider the basic model specified by Equation 15. Using standard results we can write

$$\delta = \rho_{ZQ\cdot X}\frac{\sigma_{Z\cdot X}}{\sigma_{Q\cdot X}}, \quad (19)$$

where

$\rho_{ZQ\cdot X}$ = partial correlation of Z and Q given X,
$\sigma_{Z\cdot X}^2$ = conditional variance of Z given X,

and

$\sigma_{Q\cdot X}^2$ = conditional variance of Q given X.

Further we have

$$\sigma_{Z\cdot X}^2 = \sigma_Z^2(1 - \rho_{ZX}^2) \quad (20)$$

and

$$\sigma_{Q\cdot X}^2 = \sigma_Q^2(1 - \rho_{XQ}^2) = P(1 - P)(1 - \rho_{XQ}^2). \quad (21)$$

From Equations 19, 20, and 21,

$$\delta = \rho_{ZQ\cdot X}\frac{\sigma_Z}{\sqrt{P(1 - P)}}\frac{\sqrt{1 - \rho_{ZX}^2}}{\sqrt{1 - \rho_{XQ}^2}}. \quad (22)$$

Now, using Equation 8, we can express the proportion of bias remaining after adjustment as

$$\pi = \frac{\rho_{ZQ\cdot X}}{\rho_{ZQ}}\frac{\sqrt{1 - \rho_{ZX}^2}}{\sqrt{1 - \rho_{XQ}^2}}. \quad (23)$$

Note that π may be either positive (underadjustment) or negative (overadjustment), depending on the signs of $\rho_{ZQ\cdot X}$ and ρ_{ZQ}. Moreover, $\rho_{ZQ\cdot X} = 0$ is a necessary and sufficient condition for ANCOVA to be unbiased under the model we are considering. That is, the correlation between Z and Q must be reduced to zero by conditioning on X.

Table 1
Range of π for Different Combinations of ρ_{ZQ}, ρ_{XZ}, ρ_{ZX}

Basic situation	Case	Sign (ρ_{ZQ})	Sign (ρ_{XQ})	Sign (ρ_{ZX})	π
1	1	+	+	+	$-\infty$ to +1
	2	+	−	−	$-\infty$ to +1
	3	−	+	−	$-\infty$ to +1
	4	−	−	+	$-\infty$ to +1
2	5	−	−	−	1 to $+\infty$
	6	−	+	+	1 to $+\infty$
	7	+	−	+	1 to $+\infty$
	8	+	+	−	1 to $+\infty$

Although this characterization of the condition for unbiased estimation is intuitively appealing, it is not very helpful for specifying when various π values are likely to occur in practice. However, using the definition of partial correlation, Equation 23 can be rewritten as

$$\pi = \frac{\rho_{ZQ} - \rho_{ZX}\rho_{XQ}}{\rho_{ZQ}(1 - \rho_{XQ}^2)}. \quad (24)$$

That is, we can express the proportion of bias remaining after adjustment as a function of the simple correlations among Z, X, and Q.

Suppose first that all three of these correlations are positive. Then it can be shown that $\pi < 1$, which means the initial bias will be reduced. Moreover, if ρ_{XQ} is large relative to ρ_{ZQ}, π could be very large in the negative direction. This means the adjustment can overcompensate for the initial bias. The range of possible values is $(-\infty, +1)$. A similar analysis can be undertaken for each combination of signs of the correlations. The results are presented in Table 1.

The eight cases can be classified into two basic situations. In Basic Situation 1 (Cases 1–4), the relationships are such that adjustment is in the right direction, reducing the initial bias. In Basic Situation 2 (Cases 5–8), adjustment will be in the wrong direction, further inflating the initial bias. The reason why each of the four cases in each basic situation has the same range of possible π values is that the four cases are really equivalent. Consider Case 1. Suppose we replace X by $-X$ in any Case 1 situation. We would not expect the amount of bias removed to depend

on whether X or $-X$ is used as a covariate, since both variables carry the same information. But if Z, X, and Q satisfy the conditions of Case 1, then Z, $-X$, and Q satisfy the conditions of Case 2. So each Case 2 situation may be viewed as a Case 1 situation with X replaced by $-X$. Similarly Case 3 can be generated by substituting $-Z$ for Z in Case 1 situations, and Case 4 by substituting $1 - Q$ for Q. Thus we need consider only the two basic situations.

Note that under Basic Situation 1, the initial bias increases, resulting in an estimate farther from the true value than the unadjusted mean difference. Although such bias inflation can in theory occur, it can probably be avoided in most practical situations. Often, enough is known about the general nature of selection to indicate at least the signs of the correlations among Z, X, and Q. For example, in the evaluation of compensatory education programs like Head Start (Campbell & Erlebacher, 1970), a very disadvantaged treatment group is compared with a somewhat less disadvantaged control group. For the outcomes and covariates commonly used, it can be expected that both ρ_{ZQ} and ρ_{XQ} will be negative and ρ_{ZX} positive. Under these conditions, we can be sure that Basic Situation 1 obtains, meaning that ANCOVA will underestimate the actual treatment effect.

For most practical applications of ANCOVA, Basic Situation 1 can be expected to hold. So it is of interest to consider in detail the expression for π in this case. In particular, is it possible in actual situations to say more about the range of possible π values? Because all four cases within Basic Situation 1 are equivalent in the sense described above, it suffices to consider only one case. We shall therefore assume that ρ_{ZQ}, ρ_{XQ}, and ρ_{ZX} are all positive.

Of the three correlations, only ρ_{XQ} can be estimated directly from the data. Note, however, that under our assumption of a constant treatment effect,

$$\rho_{YX\cdot Q} = \rho_{ZX\cdot Q}. \tag{25}$$

That is, $\rho_{ZX\cdot Q}$ can be estimated from the within-group relationship between Y and X, and can therefore be estimated from the data.

Using the standard formula for partial correlation

$$\rho_{ZX\cdot Q} = \frac{\rho_{ZX} - \rho_{ZQ}\rho_{XQ}}{\sqrt{(1-\rho_{ZQ}^2)(1-\rho_{XQ}^2)}}, \tag{26}$$

we obtain

$$\rho_{ZX} = \rho_{ZQ}\rho_{XQ} + \rho_{ZX\cdot Q}\sqrt{(1-\rho_{ZQ}^2)(1-\rho_{XQ}^2)}, \tag{27}$$

where the radical represents the *positive* square root. Substituting in Equation 24 yields

$$\pi = 1 - \rho_{ZX\cdot Q}\frac{\rho_{XQ}}{\rho_{ZQ}}\frac{\sqrt{1-\rho_{ZQ}^2}}{\sqrt{1-\rho_{XQ}^2}}. \tag{28}$$

So even if we can estimate ρ_{XQ} and $\rho_{ZX\cdot Q}$, we still require information on ρ_{ZQ} in order to assess π. Moreover, for fixed values of ρ_{XQ} and $\rho_{ZX\cdot Q}$, the value of π is quite sensitive to the value of ρ_{ZQ}. Since there is no constraint on ρ_{ZQ} for given values of ρ_{XQ} and $\rho_{ZX\cdot Q}$ (it can take any value between 0 and 1), we cannot place useful bounds on π in any obvious way. Only if some additional constraint on the correlations can be assumed will it be possible to restrict π to a subinterval of $(-\infty, 1)$.

Equation 28 provides another characterization of the condition for complete adjustment. All bias will be removed only if

$$\rho_{ZX\cdot Q} = \frac{\rho_{ZQ}\sqrt{1-\rho_{XQ}^2}}{\rho_{XQ}\sqrt{1-\rho_{ZQ}^2}}. \tag{29}$$

If $\rho_{ZX\cdot Q}$ is too small *or too large* there will be nonzero bias. The fact that the within-group correlation between Z and X could be too large under certain circumstances may at first appear counterintuitive. In particular, it seems plausible that ANCOVA would be unbiased when $\rho_{ZX\cdot Q} = 1$. But this will be true only if $\rho_{ZQ} = \rho_{XQ}$, or equivalently if $\rho_{ZX} = 1$. If the overall correlation between Z and X is less than 1, but the selection process results in a within-group correlation equal to 1, then adjustment will not be complete.

Equation 28 allows an intuitive understanding of the adjustment problem. If $\rho_{ZQ} > \rho_{XQ}$, the outcome (in the absence of intervention) is more strongly related to assignment than is the covariate. This means that the adjustment coefficient would have to be large in order to adjust fully, larger than β used in the analysis of covariance. If, on the other

hand, $\rho_{ZQ} < \rho_{XQ}$, then a modest adjustment coefficient is needed, and β may be either too small or too large.

In the methodological literature, a variety of potential problems in using statistical adjustment have been pointed out. I believe that all of these can be understood clearly in terms of the framework presented above. In the remainder of this article, I discuss some special issues that have received a great deal of attention. First we shall consider the problems raised by alternative models for individual growth over time on the outcome dimension. The important special case known as Lord's paradox (Lord, 1967) is analyzed in detail. Then we shall examine the situation in which covariates are measured with error, and finally we shall consider so-called regression effects.

Growth Models

Suppose the outcome of interest consists of the level of growth attained by an individual on some important dimension. Often the selection mechanism will result in a mean growth rate for the treatment group that is higher or lower than that of the controls, even in the absence of an intervention. Generally, in this situation, the covariate used is a pretest measured on the same dimension as the outcome score (posttest). In our notation, then, Y = observed posttest score, Z = posttest that would be observed without intervention, and X = pretest score. The use of statistical adjustments in this situation can be related to the voluminous literature on the measurement of change (see Cronbach & Furby, 1970), based on traditional psychometric assumptions. The problems in measuring change, from this perspective, depend primarily on reliability considerations. Much recent research on statistical adjustments when individuals are growing (Campbell & Boruch, 1975; Campbell & Erlebacher, 1970; Kenny, 1975) comes from this psychometric tradition. As a result, the problems caused by fallible measurement have been confounded with those related to growth per se. I shall discuss measurement error separately in a later section. My purpose here is to consider the problems caused by differential growth across treatment groups, even when pretests and posttests are perfectly reliable.

My analysis will follow closely that of Bryk and Weisberg (1977). They have considered various models for individual growth and for the selection of individuals into groups. With these models, they have identified situations in which various adjustments (including ANCOVA) will overadjust or underadjust.

I shall restrict consideration here to the special case when Equation 14 holds. Furthermore, it will be helpful to define standardized group differences on pretest and posttest by

$$D_Z = \frac{\mu_{Z1} - \mu_{Z0}}{\sigma_{Z\cdot Q}} \tag{30}$$

and

$$D_X = \frac{\mu_{X1} - \mu_{X0}}{\sigma_{X\cdot Q}}.$$

Then there are four basic ways that the relationship between the groups can change over time. First, the standardized distance between groups can remain the same over time. We refer to this situation as *standardized parallel growth*. Second, the standardized distance can increase. We call this situation *standardized divergence*. Third, the means may *cross over* between pretest and posttest, with the group that is higher on the pretest being lower on the posttest. Fourth, the standardized difference may decrease but not so much that crossover occurs. We then have *standardized convergence*. These four cases are illustrated in Figure 1 and summarized as follows:

I. Standardized parallel growth: $D_X = D_Z > 0.$

II. Standardized divergence: $0 < D_X < D_Z.$

III. Crossover: $D_X > 0;\quad D_Z < 0.$

IV. Standardized convergence: $D_X > D_Z > 0.$

Let us consider now what happens when the analysis of covariance is applied in each of the four cases. It will be convenient to rewrite Equation 28 in still another form:

$$\pi = 1 - \rho_{ZX\cdot Q}\frac{D_X}{D_Z}. \tag{31}$$

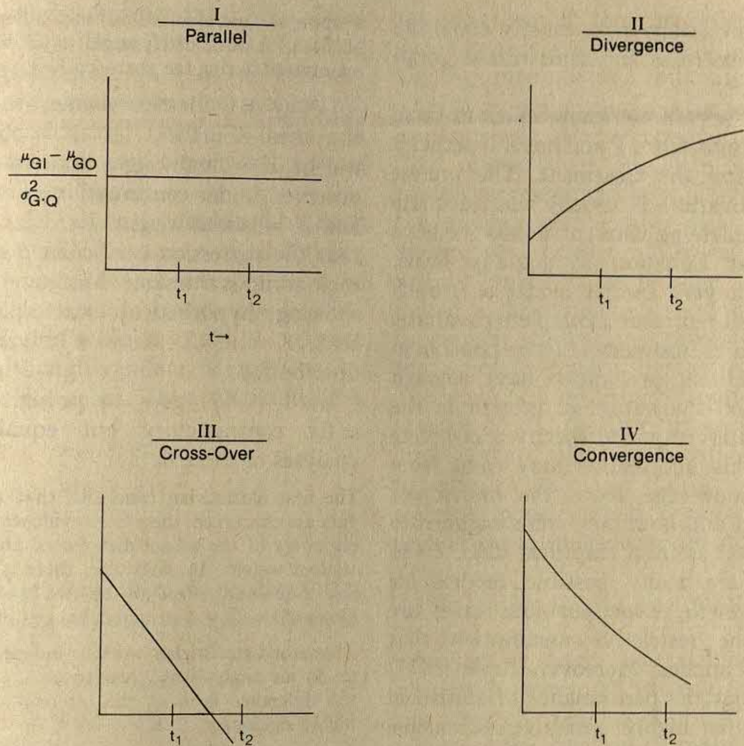

Figure 1. Types of standardized growth. [G(t) = growth at time t; t_1 = pretest time; t_2 = posttest time.]

Consider first the parallel case. From Equation 31 we obtain

$$\pi = 1 - \rho_{ZX \cdot Q}. \tag{32}$$

So in general, ANCOVA will underadjust under a parallel growth model. The special case when $\rho_{ZX \cdot Q} = 1$ and $D_X = D_Z$ is particularly interesting. It can be shown to be consistent with a "degenerate fan spread" model (Bryk & Weisberg, 1977). Under this model individual growth is represented as a straight line, and the slopes of these lines may vary across individuals, but nonnegligible growth for each begins at the same time, τ. This special situation is illustrated in Figure 2. As Bryk and Weisberg have shown, any reasonable technique will correctly adjust in this case. Because the pretest and the slope are perfectly correlated, the pretest contains full information on growth in the absence of intervention. So it constitutes a complete covariate in the sense defined above.

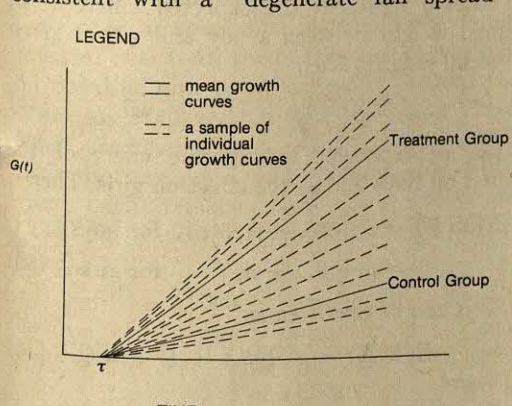

Figure 2. Degenerate fan spread. [G(t) = growth at time t.]

With a standardized divergence situation, π must be less than 1; so ANCOVA will underadjust. Under a crossover model, π will be greater than 1, and the initial bias becomes inflated. Only under the standardized convergence model does ANCOVA have the possibility of being correct. This will occur when

$$\rho_{ZX \cdot Q} = \frac{D_Z}{D_X}. \tag{33}$$

That is, the correlation between pretest and

posttest within groups must exactly equal the proportional decrease in standardized mean difference.

In general, we will not know which of these situations obtains, since Y and not Z is actually observable after the treatment. The pretest alone as a covariate is usually not adequate to allow complete adjustment unless we have evidence that Equation 33 actually holds. Only under a very special model of growth will the pretest represent a complete covariate.

If statistical adjustment is to be possible in growth situations, we must have enough information on the nature of growth in the absence of intervention to specify a complete covariate. This information may come from theoretical knowledge about the individuals being studied and how they were assigned to groups, as well as from empirical data. However, there are many possible models for individual growth. Even our four cases are all under the restrictive assumption that Equation 14 applies. Moreover, Bryk (1977) has shown that the performance of statistical adjustments is highly sensitive to model assumptions. Thus the use of statistical adjustments to control for differential growth appears quite problematic.

Lord's Paradox

Lord (1967) has presented a particularly interesting example of the problems in model specification when individuals are growing. He considered the following situation:

> A large university is interested in investigating the effects on the students of the diet provided in the university dining halls and any sex difference in these effects. Various types of data are gathered. In particular, the weight of each student at the time of his arrival in September and his weight in the following June are recorded.
>
> At the end of the school year, the data are independently examined by two statisticians. Both statisticians divide the students according to sex. The first statistician examines the mean weight of the girls at the beginning of the year and at the end of the year and finds these to be identical. On further investigation, he finds that the frequency distribution of weight for the girls at the end of the year is actually the same as it was at the beginning.
>
> He finds the same to be true for the boys. Although the weight of individual boys and girls has usually changed during the course of the year, perhaps by a considerable amount, the group of girls considered as a whole has not changed in weight, nor has the group of boys. A sort of dynamic equilibrium has been maintained during the year. (p. 304)

Let $Q = 0$ for the women and $Q = 1$ for the men. Further, let Y = observed final weight, Z = final weight that would have been observed under continuation of previous diet, and X = initial weight. Lord further assumes that the regression coefficient β of Z on X in each group is the same. Moreover, his diagram showing hypothetical scatterplots suggests that Y and X have a bivariate normal distribution.

Lord (1967) goes to present two apparently contradictory but equally plausible analyses of these data:

> The first statistician concludes that as far as these data are concerned, there is no evidence of any interesting effect of the school diet (or of anything else) on student weight. In particular, there is no evidence of any differential effect on the two sexes, since neither group shows any systematic change.
>
> The second statistician, working independently, decides to do an analysis of covariance . . .. He finds that the difference between the intercepts is statistically highly significant.
>
> The second statistician concludes as is customary in such cases, that the boys showed significantly more gain in weight than the girls when proper allowance is made for differences in initial weight between the two sexes. (p. 305)

Lord concluded that there is no way to tell from the data available which results should be accepted. He infers that in general with uncontrolled studies, there is no way to make proper allowance for differences between treatment groups.

Let δ represent the expected difference in final weight between a boy and girl of given initial weight. Then

$$E(Z|X) = \mu + \beta X + \delta Q. \tag{34}$$

Let α_1 represent the specific effect of the diet on boys and α_2 the effect on girls. Then

$$\begin{aligned} E(Y|X) &= \mu + \beta X + \delta + \alpha_1 \quad \text{for boys} \\ &= \mu + \beta X + \alpha_2 \qquad\quad \text{for girls.} \end{aligned} \tag{35}$$

This can be rewritten as

$$E(Y|X) = \mu' + \beta X + (\delta + \alpha)Q, \tag{36}$$

where

$$\mu' = \mu + \alpha_2$$

and

$$\alpha = \alpha_1 - \alpha_2. \tag{37}$$

The general model representing Lord's situation has the form of Equation 18. So estimating the differential effect $\alpha_1 - \alpha_2$ is formally identical to the usual estimation problem we have been considering. Lord's paradox can be viewed in terms of model specification along the lines developed above.

As we shall see, the data described by Lord are consistent with a variety of underlying models. One possible model corresponds to the assumption that without the change in diet, the distribution of weights would be constant over time, although random fluctuations for individuals might occur. Then we would have

$$\mu_{Z0} = \mu_{X0},$$

$$\mu_{Z1} = \mu_{X1},$$

and

$$\sigma_{Z \cdot Q}^2 = \sigma_{X \cdot Q}^2. \tag{38}$$

Suppose further that there is no treatment effect for either sex ($\alpha_1 = \alpha_2 = 0$). Then we would observe

$$\mu_{Y1} = \mu_{X1},$$

$$\mu_{Y0} = \mu_{X0},$$

and

$$\sigma_{Y \cdot Q}^2 = \sigma_{X \cdot Q}^2, \tag{39}$$

which corresponds with Lord's description of data. This model represents the first statistician's construction of the situation.

Note that under this model, $D_Z = D_X$, and we would have standardized parallel growth. Moreover, since we know that the within-group correlation between Z and X is less than 1, it follows from Equation 32 that ANCOVA will underadjust.

Suppose, however, that instead of remaining constant over time, the distribution of weights for boys and girls would change in the natural course of events, even with the same diet. There are several forms such a change could take. For example, the variance for each group might remain constant, but the mean levels move closer together. Thus we might have

$$\mu_{Z1} < \mu_{X1},$$

$$\mu_{Z0} > \mu_{X0}, \tag{40}$$

and

$$\sigma_{Z \cdot Q}^2 = \sigma_{X \cdot Q}^2.$$

This implies that $D_Z < D_X$, and we have a standardized fan close situation. From Equation 33 then, if the correlation between Z and X within groups happens to be equal to D_Z/D_X, then ANCOVA will adjust perfectly. This situation must hold if the second statistician's analysis is to be accepted.

Of course, there are many other possible models representing the underlying growth in the absence of the new diet. Under these alternatives, neither statistician's argument will be valid. It is possible that there is indeed a differential effect of diet (contrary to the first statistician's conclusion) but that the estimate proved by ANCOVA is biased. The moral of Lord's story is simply that in the absence of additional information on natural growth, there may be alternative models consistent with the data. Unless we can specify a correct model, statistical methods cannot be counted on to compensate adequately.

Covariate Measured With Error

So far we have been assuming that the covariate is measured without error. Suppose now that X represents a fallible variable subject to the usual psychometric assumptions (see Lord & Novick, 1968). The issue of reliability is very complex. Many definitions of reliability have been offered in an attempt to quantify the intuitive notion that part of an observed score is attributable to random fluctuation rather than to a stable characteristic. The effects of measurement error on statistical adjustments have been widely discussed, and many solutions to these problems have been proposed (e.g., Cochran, 1968; DeGracie & Fuller, 1972; Lord, 1960; Porter, 1967; Stroud, 1972).

The usual formulation of the measurement error problem assumes correct model specification in terms of an underlying true score T. That is,

$$E(Z|T, Q) = \mu + \beta T. \tag{41}$$

The observed score X is related to T by

$$E(X|T, Q) = T. \tag{42}$$

We define the reliability of X by

$$r = \rho_{TX \cdot Q}^2 = \frac{\sigma_{T \cdot Q}^2}{\sigma_{X \cdot Q}^2}. \tag{43}$$

Of course, in general, the conditional correla-

tions and variances may differ across groups, but to understand the main issues it suffices to consider the simple case when they are equal. In this case, it can be shown (Cochran, 1968) that the relationship between Z and X is of the form

$$E(Z|X, Q) = \mu' + \beta'X + \delta'Q, \quad (44)$$

where

$$\beta' = r\beta. \quad (45)$$

The effect of measurement error is to reduce the within-group regression coefficient (and hence the total adjustment) by a factor r. So, for example, if the reliability is .8, ANCOVA will remove 80% of the initial bias.

Based on Equation 45, methods have been proposed to estimate r and to "correct" the ANCOVA. But as noted above, this approach assumes that the model is correctly specified in terms of the true score. In general, however, there is no reason to expect that because a variable is free of measurement error it is a complete confounding factor. Instead of Equation 41 we might have

$$E(Z|T, Q) = \mu + \beta T + \delta Q \quad (46)$$

for some nonzero value of δ. In this case Equation 45 is still valid, and the reduction in bias using X remains r times the reduction in using X. So we have

$$\pi_X = (1 - r)\pi_T, \quad (47)$$

where π_X and π_T represent the proportions of bias remaining when X and T are the covariates.

This formula implies a rather curious possibility. Suppose that using T as the covariate results in an overadjustment ($\pi_T > 1$). Then by attenuating the relationship between T and Z, X may actually reduce the absolute magnitude of the remaining bias, by pulling π back toward 0. Of course, with finite samples, the use of X also implies lower precision of estimates.

With large samples, however, a variable with low reliability may be an excellent covariate. In fact, it may even be a complete confounding factor. This will occur when

$$\pi_T = \frac{1}{1 - r}, \quad (48)$$

which means $\delta' = 0$, but $\delta \neq 0$.

Although this result may seem counterintuitive, it is helpful in understanding what our definition of a complete covariate does and does not imply. It does not necessarily imply high precision with finite samples or a perfect relationship between covariate and outcome within groups. It is simply the condition under which unbiased estimation of α is possible, and implies that the model assumed by ANCOVA is correctly specified.

Note also that viewed in terms of model specification, the fallibility of the covariate is not in itself the problem. Having a perfectly reliable covariate will not guarantee correct adjustment, and having a fallible covariate does not necessarily result in bias. A fallible covariate may even be a complete confounding factor. As Overall and Woodward (1977) have emphasized, if assignment is explicitly on the basis of a fallible variable, the ANCOVA will be unbiased. A perfectly reliable variable on the other hand may not be complete. The important question is not one of measurement error, but whether Equation 15 holds in terms of whatever covariate is actually used.

Regression Artifacts

Another issue that has resulted in much confusion is the so-called *regression effect*. Suppose we wish to compare the performance of two groups on an outcome measure. The groups, however, are thought of as sampled from different populations. To adjust for differences in the groups, matching is commonly used. The problem is seen in the following terms:

> In order to get a matched group when the two populations have different mean values, we must take individuals who fall relatively high on one population and match them with individuals who fall relatively low in the other. Since the individuals in each group *will regress toward their own population mean*, the regression in the two groups will be different. Upon another test, our groups will no longer be matched. (Thorndike, 1942, p. 91)

So the mean difference on the outcome scores will differ, even if there is no difference between treatments offered to the groups. This difference is sometimes called a *regression artifact*.

This problem arises most commonly when a pretest measuring the same dimension as the outcome is used as the matching variable. The

regression artifact may then be attributed to imperfect test–retest reliability of the measuring instrument. As Thorndike (1942) noted long ago, however, the issue is much more general:

> The fallacies with which we are here concerned may arise whenever the measure or measures by means of which the groups were matched have less than a perfect correlation with the measure of the experimental variable which is being studied. A more limited example of this is found in the less than perfect correlation between a test and a subsequent retest with the same instrument. However, our argument is more general than this, and holds whenever groups are matched upon one measure or group of measures and then studied with regard to their performance on other measures which do not have a perfect correlation with the matching variable. Since this is universally true in the matched-groups experiment, the points to be raised here are of quite general application. (p. 85)

This problem is particularly confusing because it is not obvious what population mean the individuals in a group can be expected to regress toward. Suppose we know that one group is all black and the other all white. We might expect the blacks to regress toward the mean for black children. However, suppose we know they are black and living in Boston. A different mean may be relevant. This argument can be continued indefinitely. Viewed from this perspective, the concept of regression has a rather mystical quality. A retest score is being pulled by an irresistible force toward some predetermined norm from which it has deviated. Consider this convoluted argument of Campbell and Erlebacher (1970) attempting to circumvent this ambiguity:

> In situations such as this where control samples are chosen to have pretest scores equivalent to experimental samples, the question may be asked "Since the Head Start children are an extreme group, why don't they regress toward the overall population mean just as much as do the matched controls?" Comparable questions emerge when psychotherapy applicants are matched with a control sample chosen to have equally maladjusted test scores (e.g., Campbell and Stanley, 1973; 1977; pp. 11–21 and 45–50). Why are these controls expected to regress to the population mean while the therapy applicants are not? An initial answer is that person-to-person matching on individual scores involves the misleading exploitation of score instability phenomena to a much greater degree than do the complex of processes which produced the Head Start sample or the psychotherapy applicants. These groups turn out to be extreme when measured, but were not selected on the basis of their extreme scores. It is selection on the basis of extreme individual scores that creates most strongly the conditions under which obtained scores become biased estimates of true scores. (pp. 195–196)

From our standpoint, the reference to hypothetical populations is unnecessarily confusing. In any actual situation, the entire study sample may be viewed as drawn randomly from a single population to which generalizations are desired. Moreover, because we are ignoring finite-sampling issues, we can treat the sample and this population as identical.

Each individual in the population is seen as characterized by many variables. In particular, there is a value Y_i, Z_i, X_i, Q_i for individual i. In this formulation Z_i is unobservable for those individuals assigned to the treatment group, but is defined unambiguously.

With this formulation, the regression artifact is simply the bias resulting from statistical adjustment when X is not a complete confounding factor. Rather than saying that Z regresses toward two different population means, depending on which population the subject comes from, we can say that the subject's expected value of Z conditional on X depends on Q, that is,

$$E(Z|X, 1) \neq E(Z|X, 0). \tag{49}$$

An important special case that has led to much confusion occurs when Z represents a retest score on an instrument that is identical to that used for the initial test X. Suppose we are in a nonintervention situation, so that

$$Y = Z. \tag{50}$$

Then $\rho_{YX \cdot Q}$ can be interpreted as the test–retest reliability, r.

$$\rho_{YX \cdot Q} = \rho_{ZX \cdot Q} = r. \tag{51}$$

Now from Equation 28 we have

$$\pi = 1 - r. \tag{52}$$

This may be interpreted as an instance of standardized parallel growth. The underadjustment, or regression effect, is then seen as a natural consequence of this underlying growth model. On the other hand, we can assume that there exists an underlying true score T such that if the adjustment used T rather than X, there would be no remaining bias. The regression effect is then viewed as the result of measurement error.

Neither of these interpretations is *the* correct one. They are simply alternative ways of explaining the fact that the pretest does not contain complete information for adjusting posttest differences. What matters is not measurement error, differential growth, or regression toward a population mean, but simply that the relationship between posttest and pretest will not in general satisfy Equation 10.

Summary and Conclusion

I have tried in this article to provide a unified perspective on the problems in using statistical adjustments with uncontrolled selection. I have indicated how various problems can be viewed as special instances of model misspecification. In particular, problems raised by individual growth, measurement error, and regression effects can be understood in these terms.

For linear adjustment (ANCOVA), I derived an expression for π, the proportion of selection bias remaining after adjustment. This formula expresses π as a simple function of three intuitively meaningful parameters. One of these parameters, ρ_{ZQ}, expresses the relationship between the assignment process and the outcome that would be observed in the absence of the treatment. This correlation can have a substantial effect on π and cannot be estimated from data. So in general, we cannot know whether the remaining bias is likely to be small.

Unless we have evidence that X is a complete confounding factor, in the sense discussed above, we cannot be sure that all bias has been removed. As Lord (1967) has put it:

> With the data usually available for such studies, there simply is no logical or statistical procedure that can be counted on to make proper allowances for uncontrolled preexisting differences between groups. The researcher wants to know how the groups would have compared if there had been no preexisting uncontrolled differences. The usual research study of this type is attempting to answer a question that simply cannot be answered in any rigorous way on the basis of available data. (p. 305)

Many have interpreted this pessimistic conclusion as implying the need for more randomized experiments. Since adjustments cannot be counted on, methodologists must press for strict experimental control (see Campbell & Boruch, 1975).

In my view, this attitude is unrealistic. Particularly with large-scale social interventions, randomization is rarely practical. For most of our knowledge we must continue to rely on uncontrolled studies. So the crucial question is whether such studies can be better designed and analyzed. If, in Lord's words, "the data usually available for such studies" are inadequate, can we collect other data, not usually available, that will allow valid and useful inferences?

The answer depends in part on our willingness to modify the way we think about uncontrolled studies. The emphasis placed on randomized experimentation as an ideal mode of inquiry has led researchers to view alternative designs in terms of their closeness to this ideal, and to retain the idea of a treatment group versus control group comparison even when the groups have not been selected randomly. Statistical adjustments are employed in an effort to simulate the results that would have been observed under a randomized experiment. But as we have seen, the results of such attempts may be quite misleading.

Under randomization, the control group's performance is a proxy for that attained by the treatment group in the absence of intervention. With uncontrolled selection, the control group loses this property, and the rationale for such a group is greatly weakened. What is needed is a valid standard of comparison representing the outcomes for the treatment group had the treatment not been received. Information on the performance of a nonequivalent control group is relevant only if we are convinced that the groups do not really differ, or if we can specify a complete confounding factor X. Without randomization the burden of proof shifts to the investigator, who must provide evidence that two individuals with identical values of X, but assigned to different groups, would have the same outcome (on the average) in the absence of intervention.

On the other hand, it may be possible in some situations to estimate directly the performance of the treatment group in the absence of intervention, or more generally under alternative treatment conditions. This estimate can then serve as the standard of comparison against which to compare actual outcomes. For example, in some situations it

is possible to measure a characteristic of the treated population repeatedly before and after an intervention. Such repeated-measure, or time-series, designs (Campbell & Stanley, 1966; Glass, Willson, & Gottman, 1975) may allow strong causal inferences. The main threat to the validity of such designs is the possibility of a concurrent uncontrolled change at the time of the intervention. However, by applying techniques developed in single-subject research (Hersen & Barlow, 1976; Sidman, 1960), such as multiple-baseline and reversal designs, this problem can often be overcome.

Another promising approach, applicable when the outcome is a measure of developmental level, has recently been proposed (Bryk & Weisberg, 1976; Strenio, Bryk, & Weisberg, Note 3). *Value-added analysis* uses the variation in pretest scores for the treatment group to predict growth in the absence of intervention. This use of cross-sectional data to simulate the unobservable development that would have occurred without the treatment requires some strong assumptions, but these can in principle be tested using observable data. Extensions of the value-added idea to designs encompassing multiple measurements may ultimately allow valid estimates of effects on individual subjects (Strenio, Weisberg, & Bryk, Note 4).

Finally, historical information on the treated population as well as data on other relevant populations may be combined to yield reasonable standards of comparison. Bayesian and empirical Bayes approaches offer great promise as a formal technology for combining such sources of evidence (Rubin, 1978).

These approaches are not fully adequate as they now stand. They need to be refined to the point where they can produce standards of comparison that are valid under empirically testable assumptions. Attempting to develop such designs ought to be a top priority of evaluation methodologists. Until we have tried to develop alternatives not based on "approximations" to randomization, we should be cautious in discounting the value of uncontrolled studies. While statistical adjustments are certainly problematic, the potential contribution of uncontrolled studies has not really been tested.

Comparing Significance Levels of Independent Studies

Robert Rosenthal
Department of Psychology and Social Relations,
Harvard University

Donald B. Rubin
Department of Statistics,
Harvard University

Methods for comparing two or more statistical significance (p) levels are described; these methods are more rigorous, systematic, and informative than the comparisons that are commonly made by using a significant/not significant dichotomy. Formulas are provided for calculating the significance level of a comparison between two or more p levels.

Suppose that we wish to compare the results of two studies. If all that is reported for each is that the results are significant ($p \leq .05$) or not significant ($p > .05$), then the conclusion must be simply that the results are the same (both are significant, or neither is significant) or that the results differ (one is significant, and one is not significant). Most studies, however, do report information adequate for calculating p values (Rosenthal, 1978). The purpose of this article is to show how p values can be directly compared by calculating the significance level of the comparison.

Before describing our methods, two comments are in order. First, we could dichotomize each p value to be significant or not significant and use the crude method of comparison just outlined. This approach is clearly unwise because it does not use the more detailed information available in the p values. For example, a p of .05 tells about the same story as a p of .06 if both results are in the same direction and the studies are of similar size. This is true, even though many psychologists give far more credence to .05-level results than they do to .06-level results (Rosenthal & Gaito, 1963).

Our second comment on comparing ps is that if raw data or appropriate summary statistics are available, comparisons can be made that are more specific than those made solely from the p values. For example, raw effect sizes (e.g., mean differences), within-group variances, and residual variances can be directly compared with significance levels calculated for the comparisons. Since a p level is affected by raw effect size, residual variance, and sample size, the comparison of p levels is sensitive to differences in any of these components. In practice, particular areas of research tend to have reasonably homogeneous sizes of experiments, and there is substantial correlation between level of significance and magnitude of effect. For example, for eight research areas recently summarized (Rosenthal, 1976), the median correlation between effect size as measured by Cohen's d (Cohen, 1977) and the Z of the significance level was .74. Consequently, in many cases, comparisons of ps can be thought of as rough comparisons of effect sizes. Even when the sample sizes vary across the studies, however, the results presented here validly compare p values.

Notation

Consider first the simple case of two experiments, each with two treatments. Let p_j be the observed significance level in the jth experiment, and let $Z_j = Z(p_j)$ be the standard normal deviate corresponding to p_j. We assume

---

Preparation of this article was supported in part by a Fellowship from the John Simon Guggenheim Memorial Foundation to Donald B. Rubin, and by the Milton Fund of Harvard University, Biomedical Sciences Support Grant 5S07 RR 07046-12 from the National Institutes of Health to Harvard University, and the National Science Foundation.

The order of authors was determined alphabetically. Donald B. Rubin is on leave from the Educational Testing Service, Princeton, New Jersey.

Requests for reprints should be sent to Robert Rosenthal, Department of Psychology and Social Relations, Harvard University, William James Hall, 33 Kirkland Street, Cambridge, Massachusetts 02138.

that the p_j and the Z_j are directed, so that if one study shows Treatment 1 superior and the other shows Treatment 2 superior, then one p_j will be less than .5 and the other greater than .5, and one Z_j will be positive and the other negative.

Suppose that Δ_j is the parameter to be estimated in the jth experiment: $\Delta_j = \mu_{1j} - \mu_{2j}$ where μ_{ij} is the population mean of Treatment i in Experiment j.

Let $\hat{\Delta}_j = \bar{Y}_{1j} - \bar{Y}_{2j}$ be the estimate of Δ_j in the jth experiment, where $\bar{Y}_{ij}$ is the sample mean of Treatment i in Experiment j. Throughout, the symbol $\hat{}$ will be used to indicate an estimate. The standard error of $\hat{\Delta}_j$ is $\sigma_{\hat{\Delta}_j}$; if the variances of the observations in Treatments 1 and 2 are the same, say σ_j^2, then $\sigma_{\hat{\Delta}_j}$ can be written as $\sigma_j\sqrt{(1/n_{1j}) + (1/n_{2j})}$, where n_{ij} is the number of observations comprising $\bar{Y}_{ij}$. The usual estimate of σ_j^2 is the residual mean square in the jth experiment.

Comparing Two Studies

We shall now give the results and examples of their applications. The technical discussion will be postponed until the end of the article.

Result 1

Suppose

$$\frac{\Delta_1}{\sigma_{\hat{\Delta}_1}} = \frac{\Delta_2}{\sigma_{\hat{\Delta}_2}};$$

that is, suppose that the quantities estimated by the t statistics of the two experiments are the same.

Then, for large n_{ij},

$$\frac{Z_1 - Z_2}{\sqrt{2}}$$

is distributed as a standard normal deviate.

Note that the test implied by Result 1 will be sensitive to different kinds of differences between the experiments. For example, if the precisions of the two studies are the same, that is, if $\sigma_{\hat{\Delta}_1} = \sigma_{\hat{\Delta}_2}$, then the test will be able to detect the difference in raw effects. For another example, if the raw effects are nonzero but equal, that is, if $\Delta_1 = \Delta_2 \neq 0$, then the test will be able to detect different precisions; the different precisions can be due to different residual variances σ_j^2 or different sample sizes.

Table 1
Example of Comparing Two p *Levels*

Study	One-tailed p	Z
A	$1/10^7$	5.20
B	.007	2.45
Difference		2.75*

Note. Sufficiently accurate ps can usually be obtained by interpolation or by using extended tables (e.g., Federighi, 1959).
* $2.75/\sqrt{2} = Z = 1.94$; $p = .026$, one-tailed.

Example 1. Table 1 shows the results of two studies of the effects of teachers' expectations on pupils' gains in intellectual performance (Rosenthal, 1976, p. 460). In both studies, gains in performance were greater when teachers had been led to expect better performance, but Study A showed results much more significant than those of Study B, the p levels being 10^{-7} and .007, respectively (one-tailed). It is of interest to compare these p values because the children of Study A were younger than the children of Study B. The comparisons were as follows:

From a normal table we find that $Z_A = 5.20$ and $Z_B = 2.45$. Thus $Z_A - Z_B = 2.75$ and $(Z_A - Z_B)/\sqrt{2} = Z = 1.94$, $p = .026$, one-tailed, suggesting more significant results for the younger children.

Example 2. Table 2 also shows the results of two studies of the effects of teachers' expectations on pupils' gains in intellectual performance (Rosenthal, 1976, p. 460; one of these studies has already been shown in Table 1). In this example, however, the results of one study were quite significant ($p = .007$), while those of the other were not ($p = .21$). Even though these p values are quite different, the difference between these p levels has a p value of only .123. One benefit of more sys-

Table 2
Example of Comparing Two p *Levels*

Study	One-tailed p	Z
A	.007	2.45
B	.21	.81
Difference		1.64*

* $1.64/\sqrt{2} = Z = 1.16$, $p = .123$, one-tailed.

Table 3
Example of Comparing Four p *Levels*

Study	One-tailed p	Z	Linear λ	Quadratic λ	Cubic λ
Grade level					
2	$1/10^7$	5.20	+3	+1	+1
3	.0001	3.72	+1	−1	−3
4	.21	.81	−1	−1	+3
5	.007	2.45	−3	+1	−1
Statistic					
Contrast Z			2.50	1.56	1.34
$Z^2 = \chi^2(1)$			6.23	2.43	1.79
One-tailed p			.006	.059	.090

tematic comparisons of p levels will be a decrease in the tendency to assume that two studies that differ in whether their results reach some conventional level of significance are really telling different stories about the state of nature.

Comparing Many Studies

Result 2 generalizes Result 1 to the case of many experiments. For Result 2, we suppose that there are K experiments and so let the index j run from 1 to K.

Result 2

Suppose

$$\frac{\Delta_1}{\sigma\hat{\Delta}_1} = \frac{\Delta_2}{\sigma\hat{\Delta}_2} = \cdots = \frac{\Delta_K}{\sigma\hat{\Delta}_K}.$$

Then for large samples,

$$\sum_{j=1}^{K} (Z_j - \bar{Z})^2$$

is distributed as χ^2 with $K - 1$ *df*, where $\bar{Z}$ is the mean of the Z_j.

Example 3. Table 3 shows the results of four studies of teacher expectations. The first and last studies listed were of second and fifth graders, respectively, and we met them in Table 1. We met the fourth graders in Table 2. The question we now ask is whether the four p levels of Table 3 are significantly different from one another. The sum of the squares of the deviations about the mean Z (*SS*) was computed to be 10.45, which is referred to the distribution of χ^2 with 3 *df*. For the four Zs of Table 3, we found p to be .015. Alternatively, the mean square (*SS/df*) is referred to the distribution of F with 3 and ∞ *df*. For the four Zs of Table 3, we found *SS/df* to be $3.48 = F(3, \infty)$, $p = .015$.

Contrasts in the Studies

Although we know how to answer the broad question of the significance of the differences among a collection of p levels, we may often be able to ask a more focused and more useful question. For the four studies of Table 3, for example, we are far more interested in the more focused question of whether lower p levels are found more at lower grade levels. Result 3 handles such questions.

Result 3

Suppose

$$\sum_{j=1}^{K} \lambda_j \frac{\Delta_j}{\sigma\hat{\Delta}_j} = 0,$$

where

$$\sum_{j=1}^{K} \lambda_j = 0.$$

Then for large samples,

$$\frac{\sum_{j=1}^{K} \lambda_j Z_j}{\sqrt{\sum_{j=1}^{K} \lambda_j^2}}$$

is distributed as a standard normal deviate.

Example 4. The column labeled Linear λ of Table 3 gives the weights of a linear contrast to address the question of whether lower p

values are found more often at lower grade levels. The analysis showed a clear linear trend for younger children to be more significantly affected by teacher expectations, $\Sigma(\lambda_j Z_j)/\sqrt{\Sigma\lambda^2} = 11.16/\sqrt{20} = Z = 2.50$, $p = .006$ (one-tailed).

We now know that the four p levels of Table 3 differ among themselves, $\chi^2(3) = 10.45$, $p = .015$, and that there is a linear trend for the p levels to be related to grade level, $Z = 2.50$, $Z^2 = \chi^2(1) = 6.23$, $p = .006$. Since the 3 df χ^2 of 10.45 is the sum of (a) the 1 df χ^2 of 6.23 corresponding to the linear trend and (b) an independent 2 df χ^2 corresponding to deviations from the linear trend, we have that $(10.45 - 6.23) = 4.22$ is distributed as χ^2 with 2 df.

In this case $\chi^2(2) = 4.22$, $p = .121$, suggesting no strongly significant curvilinear relationships. This χ^2 of 4.22 based on 2 df can be further split into a quadratic and a cubic component. The last two columns of Table 3 show the weights (orthogonal polynomials) employed for the quadratic and cubic contrasts and the Z, χ^2, and p for each. The $\chi^2(2)$ has been split into two $\chi^2(1)$s of 2.43 and 1.79, significant at $p = .06$ and .09, respectively. Since there is no theoretical reason to expect either a quadratic or a cubic trend for the present data, we might not normally split the 2 df χ^2 further, but there are applications where such further contrasts may be of value.

Technical Discussion

To prove Results 1, 2, and 3, fix $\delta_j = \Delta_j/\sigma\hat{\Delta}_j$ at some value, and let f_j, the df in each study, get larger and larger. As $f_j \rightarrow \infty$, $Z_j = Z(p_j)$ is the t test in the jth study and thus equals $\hat{\Delta}_j/\hat{\sigma}\hat{\Delta}_j$. Furthermore, in the limit, Z_j is normally distributed with mean δ_j and variance 1. Consequently, when $\delta_1 = \delta_2$, $(Z_1 - Z_2)/\sqrt{2}$ is $N(0, 1)$ (i.e., Result 1); and more generally, when $\Sigma\lambda_j\delta_j = 0$ (where $\Sigma\lambda_j = 0$), $\Sigma\lambda_j Z_j/\sqrt{\Sigma\lambda_j^2}$ is $N(0, 1)$ (i.e., Result 3). Also, when all $\delta_j = \Delta/\sigma\hat{\Delta}$, $\Sigma(Z_j - \bar{Z})^2$ is distributed as χ^2_{k-1}, because the Z_j are independent normal variables with common mean and variance 1 (i.e., Result 2).

To obtain insight into how large each f_j should be before we can trust the above asymptotic argument, we examine the mean and variance of Z_j for large but finite f_j. Using a Taylor series expansion of an expression in Wallace (1959, p. 1121), when f_j is large Z_j can be approximated as $t_j\,(1 - t_j^2/4f_j)$, where t_j is the t statistic that was used to look up the p value, p_j. Using this approximation and assuming normally distributed data, we can use Equation 1 in Johnson and Kotz (1970, p. 203), Stirling's approximation (Wilks, 1962, p. 177), and Taylor series expansions in $1/f_j$ to show that for large f_j, the mean of Z_j is approximately $\delta_j(1 - \delta_j^2/4f_j)$ and the variance of Z_j is approximately $[1 + (\frac{1}{2} - \delta_j^2)/f_j]$. These expressions suggest that if all f_j are large enough to ensure that all values of $\delta_j^2/4f_j$ and $(\frac{1}{2} - \delta_j^2)/f_j$ are close to zero (e.g., .10), then each Z_j will essentially have mean δ_j and variance 1, as with infinite f_j; as a consequence, we then expect the asymptotic arguments leading to Results 1, 2, and 3 to be appropriate. However, in rare circumstances when f_j is so small that $\delta_j^2/4f_j$ or $(\frac{1}{2} - \delta_j^2)/f_j$ is large (e.g., .5), then the significance tests presented in Results 1, 2, and 3 may be somewhat inexact, since even when all $\delta_j = \delta$, all the Z_j will not have (a) approximately the same mean or (b) variance equal to one.

Ks Docket issue to the library 29/3/80

VOLUME 86 / NUMBER 6 NOVEMBER 1979

Psychological Bulletin

(Continued on inside back cover)

This issue completes Volume 86 and contains the author index to the volume.

PUBLISHED BIMONTHLY BY THE AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0033-2909

The *Psychological Bulletin* publishes evaluative reviews and interpretations of substantive and methodological issues in the psychological research literature. The Journal reports original research only when it illustrates some methodological problem or issue. Discussions of methodological issues should be aimed at the solution of some particular research problem on psychology, but should be of sufficient breadth to interest a wide readership among psychologists; articles of a more specialized nature can be directed to the various statistical, psychometric, and methodological journals. The *Bulletin* does not publish original theoretical articles; these should be submitted to the *Psychological Review*.

Abstracts: All articles must be preceded by an abstract of 100–175 words. Detailed instructions for preparation of abstracts appear in the *Publication Manual of the American Psychological Association* (2nd ed.), or they may be obtained from the Editor or from APA Central Office.

Blind review: Because reviewers have agreed to participate in a blind reviewing system, authors submitting manuscripts are requested to include with each copy of the manuscript a cover sheet, which shows the title of the manuscript, the name of the author or authors, the author's institutional affiliation, and the date the manuscript is submitted. The first page of the manuscript should omit the author's name and affiliation but should include the title of the manuscript and the date it is submitted. Footnotes containing information pertaining to the author's identity or affiliation should be on separate pages. Every effort should be made to see that the manuscript itself contains no clues to the author's identity.

Manuscripts: Submit manuscripts in triplicate to the Editor, R. J. Herrnstein, *Psychological Bulletin*, Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138, according to instructions provided below.

Instructions to Authors: Authors should follow the directions given in the *Publication Manual of the American Psychological Association* (2nd ed.). Instructions on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors are requested to refer to the "Guidelines for Nonsexist Language in APA Journals" (Publication Manual Change Sheet 2, *American Psychologist*, June 1977, pp. 487–494) before submitting manuscripts to this journal. All manuscripts should be submitted in triplicate and all copies should be clear, readable, and on paper of good quality. Dittoed copies are not acceptable and will not be considered. Authors are cautioned to carefully check the typing of the final copy and to retain a copy of the manuscript to guard against loss in the mail.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $40 domestic, $42 foreign, $7 single issue. APA member rate: $15. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Dept., APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in January) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036 and 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

The Construct Validity of Egocentrism

Martin E. Ford
Institute of Child Development, University of Minnesota (Minneapolis)

Construct validation is briefly explained and then applied to egocentrism. Conceptual and operational referents of this construct are organized into three categories: visual/spatial egocentrism (what does the other see), affective egocentrism (what does the other feel), and cognitive/communicative egocentrism (what is the other thinking). Several kinds of reliability information are reported, and construct validity is evaluated primarily by examination of the relationships among measures of egocentrism within and between categories. Although interrater reliability and interrater agreement were found to be uniformly high for all egocentrism measures, and the measurement reliability was usually adequate, a few tasks were not internally consistent. Overall, the construct validity of egocentrism was not supported, since most task intercorrelations were low and often nonsignificant. From this evidence and an analysis of key egocentrism tasks, an alternative interpretation of the data based on cognitive constructs and task-specific and response-specific variables is proposed.

One activity essential for progress in theory and research is the validation of psychological constructs. Essentially, a construct is an unobservable characteristic of some entity, usually a person, that is hypothesized as an explanation for some observable phenomena. Constructs usually refer to an underlying psychological structure, state, system, or process, although these are sometimes not easily specified. Examples of some common psychological constructs that fit this description are intelligence, memory, anxiety, libido, identity, attachment, and, of course, egocentrism.

The author wishes to thank Andrew Collins and Daniel Keating for their help in editing the manuscript.

Requests for reprints should be sent to Martin Ford, Institute of Child Development, 51 East River Road, University of Minnesota, Minneapolis, Minnesota 55455.

Constructs that have been adequately validated through empirical testing can be efficient and reliable sources of guidance in our problem-solving activities. On the other hand, constructs that are not valid may distort our view of the relevant problems or may lead us to seek solutions in the wrong places. It is therefore important that the validity of constructs be evaluated. Cronbach and Meehl (1955) have attempted to explain when and why it is important to evaluate construct validity in the context of psychological testing. They comment that

> *construct validation* is involved whenever a test is to be interpreted as a measure of some attribute or quality which is not "operationally defined" [i.e., there is no one operation that is by itself an adequate definition of the construct]. The problem faced by the investigator is, "What constructs account for variance in test performance?" (p. 282)

Cronbach and Meehl emphasize that construct validity can only be evaluated by

 0033-2909/79/8606-1169$00.75

integrating evidence from many different sources. They describe several kinds of investigations that can potentially provide information about the validity of a construct: (a) studies of group differences, (b) correlational and factor analytic studies, (c) studies of internal structure, (d) studies of change over occasions, and (e) studies of process.

In this article, studies that are relevant to the construct validity of egocentrism are reviewed. However, not all studies of egocentrism are included. Most of the research cited falls in the second and third categories described above, that is, correlational and internal structure studies. Where relevant to the discussion, studies of group differences (usually different age groups) are mentioned. However, since there are age differences on most measures with some cognitive content, these studies are given little weight. This kind of information is not as decisive or as discriminating as some other kinds of evidence might be and is therefore only selectively reported. For the same reason, studies of change over time might be less useful for answering questions about the construct validity of egocentrism, although this assertion is difficult to evaluate, since longitudinal studies in this area are so infrequent. Finally, studies of the psychological processes that explain or correlate with egocentric performance would probably be of great value, but unfortunately this kind of evidence is also sparse in the literature.

The article is organized around three issues:

1. What are the conceptual referents of the term *egocentrism?*

2. What are the various ways that researchers have attempted to operationalize this construct? Are these measures reliable?

3. Do the various operationalizations of egocentrism appear to be measuring the same underlying construct? If no, then what does each measure?

The present article concludes that the data do not support the construct validity of egocentrism and that several other sources of variance can be hypothesized to account for the data. Thus some additional evidence is presented that focuses primarily on the plausibility of this reinterpretation. The article relies, in particular, on an analysis of the requirements of several key egocentrism tasks and the kinds of errors that are commonly associated with them.

Conceptual Definitions of Egocentrism

Cronbach and Meehl (1955) assert that construct validation begins with a theory that defines the construct. They point out that if an investigator does not specify the meaning of the construct clearly enough, then others will be unable to evaluate the evidence provided for the validity of the construct. Although the nature of current psychological theorizing demands that a certain degree of vagueness be tolerated, the testability of a theory and the value of construct validation are greatly enhanced when this vagueness is minimized.

Another important point is that the term *egocentrism* is not always used as an explanatory construct. It is sometimes used simply to describe a specific social cognitive act and implies nothing about other acts or the underlying causes of the observed behavior. *Egocentric* may be useful as an adjective that describes a person's behavior in a given situation, but it should not be confused with the term *egocentrism* that is used to refer to a hypothetical underlying trait. It is only this latter use that is evaluated.

Looft (1972) attempted to pinpoint the meaning of egocentrism and concluded that it "does not pertain to selfishness or an overly keen regard of oneself, or even to the frequent use of 'I' or 'me.' The essential meaning of egocentrism is an embeddedness of one's own point of view" (p. 74). In Piaget's (1926) theory, which is the context in which the construct is typically used, egocentrism is defined as a lack of differentiation in some aspect of subject–object interaction. Feffer (1959, 1970) defines it as the inablity to "decenter," where decentration refers to one's ability to shift attention to consider more than one aspect of an event. Although each of these definitions is a little different, they share a common core of meaning: Each refers to an individual's failure to perceive a situation or an event in more than

one way. This one way of perceiving is the one that is easiest for the individual, that is, the one that requires no conceptual elaboration beyond what is directly perceived.

Conceptually and methodologically, the referents for egocentrism can be organized into three categories. Adapted from Shantz's (1975) review of social cognitive development, these are (a) What does the other see? (b) What does the other feel? and (c) What is the other thinking? Each of these incorporates an appreciation for perspectives other than one's own and the ability to infer in a given situation what these alternative perspectives are. The differences among these three categories are essentially in the domain each pertains to: visual/spatial (sometimes called perceptual), affective, and cognitive/communicative (sometimes called conceptual).

Piaget's theory and the current developmental literature imply that egocentrism is a characteristic of individuals that is both consistent across situations and stable over time. Because egocentric performance is typically regarded as an indication of the developmental status of the individual in terms of Piaget's stages of cognitive development, egocentrism is clearly meant to refer to a generalized trait. In other words, the presence or absence of this hypothetical construct is considered to be a sufficient explanation for the presence or absence of a wide range of phenotypically diverse behavior. The major prediction that one can make from this conceptualization is that if egocentrism is a unitary trait that can be used to predict failures in all kinds of perspective taking, then measures of egocentrism from each of the three domains previously described should be positively and significantly correlated. It is reasonable to expect that correlations of measures within a given domain would be higher than those between categories (due to domain specific variance), but both sets of correlations should exceed correlations between egocentrism measures and measures of other constructs. Although these latter correlations may be expected to be positive and significant for theoretically related constructs such as intelligence, conservation, and popularity (Rubin, 1973), they should not equal or exceed within-construct correlations.

In the section on Relationships Among Egocentrism Measures, studies that have computed these kinds of correlations are reviewed. First, however, the next section describes operational definitions (measures) of egocentrism and reports evidence on the stability and internal consistency of these measures.

Operational Definitions of Egocentrism

Measures of Visual/Spatial Egocentrism: What Does the Other See?

Piaget and Inhelder (1956) developed the first measure that was intended to assess the ability to imagine how an object or set of objects would appear from a different occupied position (i.e., from the perspective of another person). In their test, known as the three-mountains problem, a child sits in one of four chairs positioned around a table on which three mountain-shaped objects are placed. A doll is placed in one of the three vacant chairs, and the child indicates what the doll sees by pointing to one of a set of drawings or photographs, by drawing what the doll sees, or by recreating the doll's view by manipulating materials provided to the child. A correct response is taken as evidence for visual/spatial perspective-taking ability.

Many innovations on this task have appeared in the literature; various stimulus displays have differed fundamentally on dimensions of complexity and familiarity. Flavell, Botkin, Fry, Wright, and Jarvis (1968) developed several measures, including one in which four displays are presented one at a time in a standard sequence. Each display consists of a set of objects fastened to a board, which is placed in the middle of a small rectangular table. These displays are increasingly complex: The first has only a single red wedge of wood; the second consists of three vertically oriented blue cylinders of equal height; and the last two displays, one blue and the other half red and half blue, consist of three cylinders of unequal height. The child's task is to reconstruct the experimenter's visual perspective using a duplicate set of unfastened objects.

Many other visual/spatial role-taking tasks could be described; brief characterizations of some of these should suffice. In a simple task, Liben (1978) had young children wearing yellow sunglasses indicate how a white card would appear to an experimenter wearing green sunglasses. Coie, Costanzo, and Farnill (1973) used a display in which a toy doll was oriented in different positions with respect to three toy houses varying in both size and color. Kurdek and Rodgon (1975) created a display with presumably attractive and familiar Walt Disney characters. Photographs, including several on a photo cube, and a table setting were used by Zahn-Waxler, Radke-Yarrow, and Brady-Smith (1977), based on measures developed by Flavell et al. (1968). Fishbein, Lewis, and Keiffer (1972) displayed either one or three toys to a child, who either pointed to one of a set of four or eight photographs or actually turned the display until the correct view was facing towards the child. Eliot and Dayton (1976) used an adaptation of the three-mountains task; by varying the shape of the stimulus objects (blocks) and the shape of the board that supported them and by varying as well the arrangement of the objects, 39 different configurations could be constructed. Finally, Shantz and Watson (1971) had young children view a display in a covered box and then view the same display from the opposite side; on some trials the display was rotated 180° and the children's expressions of surprise or amusement were noted.

It is important to note that in all of these measures, only certain responses can be interpreted as a manifestation of egocentrism, that is, those that represent the actual visual/spatial perspective of the subject. All other errors are nonegocentric errors because they represent perspectives other than those experienced by the subject. For example, it would not be evidence of egocentrism if a child, when asked to show how someone sitting opposite the child would see a rectangular display, were to indicate a perspective that was incorrect but different from his or her own, such as the perspective of someone sitting to the immediate right. No matter how poorly the child performs on the task, egocentrism can only logically be inferred when the child's own perspective is offered as the correct answer. This point is elaborated in a later section in which age differences in visual/spatial perspective-taking errors are considered.

Reliability. Only one estimate of the reliability of any measure of visual/spatial egocentrism appears in the published literature. Rubin (1973) reports that test-retest (TR) reliability for the Flavell et al. (1968) measure is between .85 and .95 for his sample of 5- to 12-year-olds. Where reported, the interrater reliability and interrater agreement have also been in this range (Rubin, 1973; Zahn-Waxler et al., 1977).

Measures of Affective Egocentrism: What Does the Other Feel?

Affective egocentrism refers here to an inability to infer the feelings of others. It does not imply the ability or inclination to share these feelings, which distinguishes it from a related construct, empathy. (In general, taking the perspective of another person requires being able to identify and appreciate a different view of the world in some domain. It does not require that this perspective be experienced in precisely the same way; indeed, that would be unlikely, since immediately perceived and inferred experience would have to be equivalent.)

In one widely used measure of affective egocentrism, Borke's (1971, 1973) Interpersonal Perception Test, a child is told a short story that portrays an emotionally stimulating situation, such as losing a pet (sadness), going to a birthday party (happiness), having a toy broken by another child (anger), and being lost (fear). There are 23 stories in all. Presented along with these stories is a picture of the described situation, in which the appropriate character has a blank face. The child's task is to supply the proper facial expression. A similar but even simpler measure was used by Feshbach and Roe (1968), whose Affective Situations Test provided the appropriate facial expressions for the story characters along with the situational cues. An important criticism of these

measures is that one cannot be sure that correct responses are evidence of true perspective taking, since there is no clear criterion for discriminating between subjects' attributing their own responses to a situation and actually inferring the emotional responses of another.

A measure of affective egocentrism that may permit this discrimination was developed by Rothenberg (1970). This task differs from Borke's Interpersonal Perception Test on dimensions of familiarity and to a lesser degree, complexity. For this measure, children are required to judge the feelings of individuals unlike themselves (adults) in relatively unfamiliar situations (e.g., unexpectedly bringing friends home for dinner to an unprepared spouse). This task is more complex in that no visual cues are available and the taped verbalizations are more adultlike and presumably more difficult to comprehend.

Several researchers (Burns & Cavey, 1957; Deutsch, 1974; Kurdek & Rodgon, 1975) have used the general strategy of presenting pictures or films of situations in which the facial expression of the central character is not what one would expect on the basis of the contextual cues (e.g., frowning at a birthday party or following a helpful gesture by another). Inferring affective perspective taking in these tasks is difficult, since children with the ability to infer the feelings of others may give differing responses depending on individual differences in the salience of the incongruent facial and situational cues. The problem mentioned earlier of discriminating attribution of one's own feelings and inferring others' feelings is here also.

Reliability. Only three studies report measurement reliabilities for affective egocentrism, and all are dangerously low. For a sample of third and fifth graders, the internal consistency of the Rothenberg measure has been reported as .28–.47 (Rothenberg, 1970), .30 (Hudson, 1978), and .50 (Rubin, 1978). In the latter study, the internal consistencies within Grade Levels 1, 3, and 5 were only .18, .20, and .39, respectively. Again, where reported, interrater reliability and interrater agreement are fairly high (Hudson, 1978; Moir, 1974; Rothenberg, 1970; Rubin, 1978).

Measures of Cognitive/Communicative Egocentrism: What Is the Other Thinking?

This is the broadest of the three categories and is therefore not as conceptually distinct as the previous two. In general, this set of tasks requires the subject to infer something about the thoughts, motives, or intentions of another person. Sometimes this is done more or less in the absence of the subject's potentially interfering cognitions, but more commonly the evidence of interest is whether one can overcome the tendency to attribute one's own knowledge to another in some sort of communicative situation.

Referential communication. Perhaps the most widely used measures of cognitive/communicative egocentrism are those used in referential communication studies, in which a listener must select the appropriate object (referent) from a set of objects (nonreferents) on the basis of a verbal message by a speaker. In some cases the major dependent variable is the number of successful matches made by the speaker and listener, although since the characteristics of the listener can vary considerably, others have been more interested in the actual content of the speaker's message. This also provides a more direct assessment of the subject's communicative ability. The most widely used measure of referential communication ability was devised by Glucksberg and his colleagues (Glucksberg & Krauss, 1967; Glucksberg, Krauss, & Higgins, 1975; Glucksberg, Krauss, & Weisberg, 1966). In this task, a speaker and a listener are seated at opposite ends of a table with an opaque screen separating them. Several stimuli are pictured on cards or blocks; these stimuli are novel graphic designs that are difficult to label or describe. The speaker then attempts to provide descriptions of each stimulus so that the listener can successfully discriminate the referent from the nonreferents. Successive trials are not independent in the sense that the set of nonreferents diminishes in size with each trial, although some researchers have used the full set of stimuli for each trial. A variant on the general Glucksberg et al. procedure is to have listeners provide feedback indicating that they didn't understand the first message and then

to assess how the speaker's communication is affected. This manipulation is based on the premise that egocentric speakers will be unable to recode the message to take into account the communicative failure.

Other measures have been devised to assess referential communication ability, and in a situation analogous to that for the visual/spatial and affective egocentrism measures, these differ essentially in the familiarity and perceptual complexity of the stimulus items used. In addition to the Krauss and Glucksberg Blocks Task (Krauss & Glucksberg, 1969), Piché, Michlin, Rubin, and Johnson (1975) administered the Baldwin and Garvey Picture Identification Task (Baldwin & Garvey, Note 1), in which subjects describe a picture of a Dr. Seuss-like animal to a listener who must select the correct picture from a set of seven that closely resemble each other. Piché et al. (1975) also administered the Crystal Climbers Task, in which subjects describe a model made of white plastic circles, squares, rectangles, and cylinders of various sizes to a listener who must construct the same model out of a set of unassembled pieces. Other studies used measures of less perceptual and conceptual complexity. Shatz and Gelman (1973) had their subjects describe which of several airplanes of similar appearance to choose. Maratsos (1973) had young children describe to an experimenter who either was watching or who could apparently not see (i.e., hands over eyes but with a small crack to peek through) which of several toys to place in a toy car that the child was to catch as it rolled down a small hill. These toys consisted of familiar, easily discriminable and describable objects: a red duck, a green duck, small dogs, and boys and girls. Hoy (1975) also varied whether the listener could see the speaker, but in addition the familiarity and complexity of the objects to be described were manipulated (i.e., a horse or a random shape).

Social and private speech. Another method of assessing cognitive/communicative egocentrism is to observe the quality of children's speech in naturalistic settings. These settings may be social, in which case the data of interest are the degree to which speakers can modify their messages according to the status of their listeners, especially those who are younger and presumably less competent communicators (Garvey & Hogan, 1973; Shatz & Gelman, 1973). In other instances, these settings may be mostly nonsocial in the sense that any speech that occurs is not directed at another person. This measure clearly originated from Piaget's (1926) characterization of the speech of young children as repetitious and like a "collective monologue." Kohlberg, Yaeger, and Hjertholm (1968) developed a quantitative scale in which certain kinds of private speech, such as the repetition of words for their own sake or simple descriptions of one's own ongoing activity, were rated as more egocentric than other kinds of private speech, such as speech that was used to guide and control activity or inaudible muttering. This kind of measure seems to be an indirect means of assessing the ability to infer the cognitive perspective of another and to adjust one's behavior accordingly. Social speech measures might be better suited to this purpose. However, Kohlberg et al. comment that self-communication may not be very different from social communication with someone you know intimately.

Feffer's Role-Taking Task. A third popular kind of cognitive/communicative egocentrism measure is Feffer's Role-Taking Task (RTT; Feffer, 1959, 1970; Feffer & Gourevitch, 1960; Feffer & Suchotliff, 1966). This measure, which attempts to tap an individual's ability to decenter or to see an interpersonal situation from the perspective of another, requires subjects to make up an initial story as one character would tell it from a picture (e.g., a Thematic Apperception Test card) that portrays at least three characters. Then they must retell the story as it would be perceived or experienced by the other characters, repeating the story once for each character. Scoring is based on the extent to which the sequential story telling reflects an ability to logically coordinate the different versions of the initial story and to elaborate the roles and internal states of the characters (Schnall & Feffer, Note 2).

Privileged information. A fourth measurement strategy in this domain is the privileged

information paradigm originated by Flavell et al. (1968) and further developed by Chandler (1973). Flavell's version, known as the apple-dog story, is similar to Chandler's several stories. Subjects first describe a story that is displayed in a sequence of several cartoons that depict story characters in emotionally charged and stressful situations. They then must retell the story from the perspective of a bystander who has no knowledge of the activity portrayed in an important subset of the cartoons. This knowledge is crucial for understanding the outcome of the story and is the subject's "privileged information" that must not be attributed to the bystander if successful role taking is to occur. Scoring is based on the degree to which subjects are able to restrict their second narrative to the limited perspective of the bystander. Ambron and Irwin (Note 3) used a similar strategy, except that in their test the narrative is supplied by the experimenter, and there are fewer cartoons (four).

Chandler, Helm, and Smith (Note 4) developed a task based on "droodles," which are clever drawings that convey some situation with a minimum of lines. Subjects first saw only a part of the droodle, which by itself was uninterpretable, and then were given the whole drawing. The task was then to interpret the picture from the perspective of someone who had only seen the uninterpretable part of the droodle.

Zahn-Waxler et al. (1977) used a wide array of tasks that assessed conceptual role taking, including two privileged information stories. However, they also included tasks that involved (a) choosing an appropriate birthday gift for other persons; (b) choosing the appropriately sized chair for one's self and for an adult experimenter; (c) indicating which of two games, including one that a confederate preferred and the subject did not prefer, that the confederate would like to play with; and (d) indicating which of two foods (attractive cookies or juice with soggy crackers) that a confederate who pretended to hate cookies would prefer to eat.

Recursive thought. Another means used to assess cognitive/communicative egocentrism is through the child's understanding of the recursive nature of thought (Miller, Kessel, & Flavell, 1970). This measure involves showing subjects several cartoonlike drawings in which scalloped cartoon clouds represent thinking and smooth cartoon clouds represent talking. The faces of a boy, a girl, a mother, and/or a father are pictured in the drawings. Different configurations of smooth and scalloped clouds are embedded in one large scalloped cloud, indicating that the depicted character is thinking about something. After subjects are trained to understand the meaning of the clouds, they are asked to describe what the person in the picture is thinking. The pictures to be described range from relatively simple situations (e.g., the boy is thinking about the girl) to fairly complex representations (e.g., the boy is thinking that the girl is thinking of him talking to her). Presumably, an inability to take the perspective of another will be reflected in an inability to describe events such as thinking about another's thoughts.

Infer game strategies. A sixth and final set of measures in this domain are those that require subjects to infer the strategy of an opponent in a game. The most widely used of these is the Flavell et al. (1968) nickel–dime game, in which the subject has a nickel and a dime and two upside-down cups with another nickel and dime taped to them. The subjects' instructions are to cover the coins with the pair of cups in such a way that their opponents will choose the lesser of the two rewards. For each trial, subjects may be asked to explain their rationale for the placement of the cups. These explanations are analyzed for the degree to which they reflect consideration of the thought processes (i.e., strategies) of the opponent. The hide-the-penny guessing game used by Selman (1971a, 1971b) is similar in purpose and execution.

Reliability. Relatively abundant reliability information is available for the various measures of cognitive/communicative egocentrism. The three studies that provide measurement reliabilities for referential communication tasks report TR correlations of .86 (Chandler, Greenspan, & Barenbaum, 1974), .89 (Deutsch, 1974), and .85–.95 (Rubin, 1973), which indicates that this is a

fairly reliable measure. Rubin also found that the reliability (TR) of the private speech and recursive thought measures was adequate (.85–.95). However, Kohlberg et al. (1968) reported a TR correlation of only .43 for their measure of private speech. Similarly low reliabilities are reported for Feffer's RTT. All four studies that reported reliability coefficients obtained low internal consistency estimates: .27 (Keller, 1976), .40 (Kurdek, 1977), .40 (Turnure, 1975), and .42 (Feffer & Gourevitch, 1960). Kurdek also obtained a TR correlation for this task of .60. On the other hand, Chandler's privileged information stories are more reliable, although not dramatically so. Internal consistency reliabilities of .91 (Chandler et al., 1974), .65-.86 (O'Connor, Note 5), .56 (Kurdek, 1977), and .52 (Rubin, 1978) have been reported. Chandler et al. and Kurdek obtained TR correlations of .84 and .68, respectively. And finally, O'Connor and Kurdek reported adequate internal consistency (.77–.85 and .68) for two different game strategy inference measures.

Interrater reliability and interrater agreement are uniformly high for all of the above measures, indicating that scoring is not a major problem (Byrne, 1974; Chandler & Greenspan, 1972; Chandler et al., 1974; Deutsch, 1974; Feffer, 1959; Hudson, 1978; Kohlberg et al., 1968; Kurdek, 1977; Leahy & Huard, 1976; Piché et al., 1975; Rubin, 1972, 1974, 1978; Turnure, 1975; Urberg & Docherty, 1976; Weinheimer, 1972; Wolfe, 1963; Zahn-Waxler et al., 1977; Marsh & Serafica, Note 6; Olejnik, Note 7). Unfortunately, some of these reliability estimates are difficult to evaluate, since the actual degree of rater independence is often unknown because the scoring procedures are not described in sufficient detail.

Summary. The various measures of egocentrism can be organized into three categories that correspond to their conceptual referents. The major dimensions that differentiate measures within categories are the familiarity of the task stimuli and the complexity of the task in terms of its perceptual characteristics, the task instructions, and the type of response required. The main dimension that differentiates measures between categories is the kind of inference required. (i.e., Is it concerned with seeing, feeling, or thinking?) Visual/spatial egocentrism measures are patterned after Piaget and Inhelder's (1956) three-mountains problem, but there are many variations ranging from simple displays with familiar objects to fairly complex displays with novel objects. Not all errors on these tasks are egocentric errors. Affective egocentrism measures are fewer in number, but these have special problems that relate to the kind of inferences that can legitimately be made about subjects' thought processes (e.g., memory vs. perspective taking). Also, the internal consistency of these measures appears to be lower than one would like, indicating that the shared variance among task items is minimal. There are many different kinds of cognitive/communicative egocentrism measures, including referential communication measures, observational measures of children's naturalistic speech, Feffer's RTT, measures that assess appreciation of privileged information and comprehension of recursive thought, and measures that assess awareness of another's strategies in a game situation. Where reported, reliabilities seem to be at least moderately high for all of the measures in this category except Feffer's RTT, the internal consistency of which is too low to claim that it reliably measures a unitary dimension.

Relationships Among Egocentrism Measures

Tables 1, 2, and 3 summarize the data reviewed in this section and the last section that is relevant to the construct validity and reliability of measures of egocentrism. In these matrices of correlations, four kinds of reliabilities are indicated. Two refer to the reliability of the measure itself, TR and internal consistency (IC). The other two refer to the reliability of the judges who scored the egocentrism measures, interrater reliability (IR) and interrater agreement (IA).

The row (and column) labeled Other conceptual role-taking tasks (Tables 1 and 3) refers to a wide variety of tasks not subsumed by the other categories. These include a word association test (Piché et al., 1975), one of

the many Flavell et al. (1968) tasks (Moir, 1974), the conceptual role-taking tasks described in the previous section that were used by Zahn-Waxler et al. (1977), and a task devised by Selman in which one must infer the thoughts and intentions of a filmstrip character (Kurdek, 1977). Included in Tables 1-3 are several constructs other than egocentrism, so discriminant validity can be evaluated as well as convergent validity.

The data presented in Tables 1–3 should be interpreted with great caution. These tables are an organizational device and not the final word on the construct validity of egocentrism. Correlations are not the only kind of relevant evidence. The data in Tables 1–3 will be more meaningful if one has a grasp of the rationale for each study, the specific procedures used, the situation in which the testing took place, and so forth, which can be obtained from the original reference. Nevertheless, these tables should be a convenient starting point for those interested in investigating the construct validity of egocentrism.

Visual/Spatial Egocentrism and Affective Egocentrism

Using two of the Flavell et al. (1968) visual/spatial measures and Rothenberg's affective egocentrism measure, Moir (1974) found in a sample of 40 11-year-old New Zealand girls essentially zero correlations between the two domains after IQ was partialed out. One of the two correlations was significant ($r = .36$, $p < .05$) before partialing out IQ. Rubin and Maioni (1975), using an adapted version of the three-mountains problem and Borke's affective egocentrism task, obtained a correlation of .44, which was not significant for their small sample of 16 preschool children. The only other study to relate measures in these two domains (Kurdek & Rodgon, 1975) correlated scores on a visual/spatial task that involved three Walt Disney characters and a task that required identification of affective states in situations in which facial and contextual cues were incongruent. In their large sample ($N = 167$) of children from Grades K, 2, 4, and 6, the correlation between the two tasks was significant only for second graders, and even there it did not account for a large portion of the variance ($r = .36$).

One can tentatively conclude that the proportion of variance shared by these two domains is small indeed and is possibly attributable to general intelligence. One certainly cannot conclude from these data that an underlying construct of egocentrism can explain individual differences on these tasks. This conclusion must remain tentative, however, because the internal consistency of the affective egocentrism measures is so low that it may preclude obtaining high validity correlations. Although this may be a function of the hypothesized trait being measured, it may be a measurement failure. The question of what visual/spatial and affective egocentrism tasks might be measuring if not egocentrism is dealt with later.

Affective Egocentrism and Cognitive/Communicative Egocentrism

Only a few studies have correlated measures in these two domains, and these substantially support the conclusions advanced previously. Using a sample of 73 delinquents and nondelinquent controls, Rotenberg (1974) found a correlation of .02 between a cognitive role-taking measure that assessed subjects' ability to predict other's everyday behavior and an affective role-taking measure that assessed their tendency to relieve the distress of others. Hudson (1978) reported a small but significant relationship ($r = .16$) between Rothenberg's affective egocentrism measure and Flavell's apple-dog story. Similarly, Rubin (1978) found partial correlations (controlling for chronological age) of $-.23$ and .00 between Chandler's privileged information stories and the Rothenberg and Borke measures, respectively. Rubin also reported mostly nonsignificant partial correlations between these affective egocentrism measures and the hide-the-penny game, the Glucksberg-Krauss task, and the Miller et al. recursive thought measure, although these latter two were significantly related to Rothenberg's task ($r = .25$ and .20, respectively).

Table 1
Construct Validity and Reliability of Measures of Egocentrism

Measure	Visual/spatial egocentrism	Affective egocentrism	Referential communication	Recursive thought
Visual/spatial egocentrism	TR = .85–.95 [*N* = 10, 5–12(24)] IR = .82–.95 [*N* = 20, 5–12(24)] IA = 86%–100% [*N* = 108, 3–7(36)]			
Affective egocentrism	.44 [*N* = 16, 3–5(27)] .36* (.01) [*N* = 40, 11(17)] .24 (.02) [*N* = 40, 11(17)] .36* at one grade, *ns* at other three grades [*N* = 167, 5–12(14)]	IC = .28–.47 [*N* = 40, 11(17)] IC = .30 [*N* = 110, 7–8(10)] IC = .50 [*N* = 12, 3–11(26)] IR = .91 [*N* = 108, 8–11(22)] IA = 90% [*N* = 110, 7–8(10)] IA = 85% [*N* = 40, 11(17)] IA = 100% [*N* = 12, 3–11(26)] IA = 81% [*N* = 12, 3–11(26)]		
Referential communication	.65* (.35*) [*N* = 80, 5–12(24)] .49* [*N* = 112, 8–76(25)] *sig* at one of two ages [*N* = 74; 8, 12(9)]	(.06) [*N* = 63, 3–11(26)] (.25*) [*N* = 142, 3–11(26)]	TR = .91 [*N* = 10, 5–12(24)] TR = .86 [*N* = 125, 8–15(4)] IR = .98 [*N* = 80, 5–12(23)] IR = .96 [*N* = 68, 9–12(15)]

Note. TR = test–retest reliability; IC = internal consistency; IR = interrater reliability; IA = interrater agreement. Each entry is in the general form: r(partial r) [N = X, ages(reference key number)], where r is the correlation between two sets of scores, partial r is the same correlation with IQ, mental age, or chronological age partialed out, N is the number of subjects in the study, ages is the ages (in years) of groups used to compute the correlations, and reference represents a number in the following reference key: 1 = Bunting (1975); 2 = Byrne (1974); 3 = Chandler & Greenspan (1972); 4 = Chandler, Greenspan, & Barenbaum (1974); 5 = Deutsch (1974); 6 = Feffer (1959); 7 = Feffer & Gourevitch (1960); 8 = Feffer & Suchotliff (1966); 9 = Heilbrunn (1974); 10 = Hudson (1978); 11 = Keller (1976); 12 = Kohlberg, Yaeger, & Hjertholm (1968); 13 = Kurdek (1977); 14 = Kurdek & Rodgon (1975); 15 = Leahy &Huard (1976); 16 = Marsh & Serafica (Note 6); 17 = Moir (1974); 18 = O'Connor (Note 5); 19 = Olejnik (Note 7); 20 = Piché, Michlin, Rubin, & Johnson (1975); 21 = Rotenberg (1974); 22 = Rothenberg (1970); 23 = Rubin (1972); 24 = Rubin (1973); 25 = Rubin (1974); 26 = Rubin (1978); 27 = Rubin & Maioni (1975); 28 = Rubin & Schneider (1973); 29 = Selman (1971); 30 = Selman & Lieberman (1975); 31 = Sullivan & Hunt (1967); 32 = Turnure (1975); 33 = Urberg & Docherty (1976); 34 = Weinheimer (1972); 35 = Wolfe (1963); 36 = Zahn-Waxler, Radke-Yarrow, & Brady-Smith (1977). In most cases, no partial r was computed, so it does not appear in the entry. Some studies reported a range of correlations, and most used several separate age groups. IA is expressed as a percentage rather than as a correlation.

* $p < .05$, except for IA. Studies that reported only whether a correlation was significant or nonsignificant are denoted *sig* or *ns*.

Another study that found a modest but significant relation between the affective and cognitive/communicative domains (Moir, 1974) reported a correlation of .49 between Rothenberg's task and a game strategy inference measure. With IQ partialed out, the correlation was still significant ($r = .35$). One possible interpretation of these relationships is that some of these measures may be tapping some common social cognitive or personality dimension such as social insight or social sensitivity. However, without more validity information this hypothesis is little more than speculation. The alternative hypothesis that performance on perspective-taking measures in the affective and cognitive/communicative domains can be explained by an underlying construct of egocentrism is, as it was for the visual/spatial and affective domains, untenable.

Visual/Spatial Egocentrism and Cognitive/Communicative Egocentrism

A set of three studies that related visual/spatial and referential communication measures shows a fairly consistent pattern of significant correlations. Rubin (1973) obtained a correlation of .65 between Flavell's four displays and the Glucksberg-Krauss task on a sample of 80 children aged 5–12. With IQ partialed out, the correlation was considerably lower but still significant ($r = .35$). In another study of 112 children in grades two and six and college-aged and elderly adults, Rubin (1974) found a correlation of .49 between the same two tasks, although the correlation within ages was only significant for the sixth graders and undergraduates. Heilbrunn (1974) found a significant correlation for 8-year-olds but not for 12-year-olds between performance on a modified version of the three-mountains task and a referential communication task. These studies together suggest that there may be a common underlying construct that weakly ties the two sets of measures together.

Do other cognitive/communicative egocentrism measures show a similar relationship with visual/spatial egocentrism? With one possible exception, the answer seems to be no. Sullivan and Hunt (1967) found correla-

Note. TR = test–retest reliability; IC = internal consistency; IR = interrater reliability; IA = interrater agreement. For an explanation of the form of each entry, see Table 1 *Note.*
* $p < .05$, except for IA. Studies that reported only whether a correlation was significant or nonsignificant are denoted *sig* or *ns*.

tions of .25, .00, and .35 between the three-mountains task and Feffer's RTT at ages 7, 9, and 11, respectively. Heilbrunn similarly found no relationship at age 8 and a significant but modest correlation at age 12. Considering the poor internal consistency of the Feffer measure, it is not surprising that these correlations are unimpressive. The only study that correlated visual/spatial and privileged information tasks, Kurdek and Rodgon's (1975) study of 167 children from kindergarten to sixth grade, found nonsignificant correlations at all ages except grade five, which may be attributable to chance, considering the number of correlations computed. Moir (1974) found that one of two visual/spatial tasks was significantly correlated with Selman's measure of inferring game strategies, but Selman (1971b), using a sample of 60 preadolescents, did not obtain a significant relationship between his measure and two scores from a different visual/spatial perspective task. Rubin (1973) found a nonsignificant correlation of .28 (with IQ partialed out, −.06) between private speech and visual/spatial egocentrism. It seems that the only egocentrism measure other than referential communication that might be significantly related to visual/spatial perspective taking is comprehension of recursive thought; Rubin (1973) found a correlation of .73 (with IQ partialed out, a still significant .36) between these two measures.

Within-Domain Correlations for Cognitive/Communicative Egocentrism

Correlations among the various cognitive/communicative egocentrism tasks support the hypothesis that referential communication and recursive thought, along with visual/spatial perspective taking, form a cluster of measures that share some reliable variance beyond general intelligence and are more or less unrelated to other measures in this domain. Rubin (1973) found a correlation between measures of referential communication and recursive thought of .72, which remained significant when IQ was partialed out ($r = .31$). In Rubin's (1978) study, this finding was replicated (partial $r = .46$). In these two studies Rubin also found that neither measure was consistently related to private speech, the hide-the-penny game or Chandler's privileged information stories. In a sample of 20 fourth graders, Piché et al. (1975) also found nonsignificant correlations between Feffer's RTT and two referential communication tasks ($r = .23$ and $-.08$, respectively). However, one of these latter two measures, the Crystal Climbers Task, was significantly related to Chandler's stories ($r = .44$), although the other, the Baldwin and Garvey Picture Identification Task, was not ($r = .32$). Similarly, Chandler et al. (1974) found a modest but significant correlation of .31 between the privileged information stories and a referential communication task, whereas Leahy and Huard (1976) obtained a correlation of only .05. None of the above three studies controlled for age or IQ, which probably accounts for some of the small amount of shared variance between these two sets of measures. For example, Rubin (1978) obtained a significant *negative* correlation ($r = -.25$) between the Chandler and Glucksberg-Krauss tasks when chronological age was partialed out. Chandler's stories also do not consistently relate to Feffer's RTT (Kurdek, 1977; Piché et al., 1975), although low but significant correlations are reported by Kurdek between Chandler's stories and Flavell's nickel–dime game and between Feffer's RTT and the nickel–dime game. An important and revealing exception to this general pattern of low correlations among cognitive/communicative egocentrism measures is the Kohlberg et al. (1968) finding that private and social speech are highly correlated ($r = .68$). These measures probably reflect a general level of maturity in the use of language.

Interpretation and a Hypothesis

From these data one can argue that if there is a construct of egocentrism underlying performance on these tasks, it is not manifested on other than the visual/spatial, referential communication, and recursive thought measures. Even this conclusion is tentative, since it rests heavily on one study, and much of the shared variance among these tasks is attributable to general intelli-

gence. One might note that Rubin's (1973) factor analysis of these three measures, private speech, conservation, popularity, and chronological and mental age yielded two factors that are easily identifiable as general intelligence and popularity factors despite the fact that Rubin labeled the first factor an egocentrism factor. (This factor had high positive loadings from all variables except popularity.) Still, the modest but perhaps unexpected relationship among visual/spatial, referential communication, and recursive thought measures, if replicable, must be accounted for. Although egocentrism is one possible explanation, it is unparsimonious, since it fails to account for the predominantly nonsignificant correlations between these three tasks and other cognitive/communicative (as well as affective) egocentrism measures.

One can entertain the hypothesis that these measures are related beyond their simple relationship with general intelligence primarily because they share a property usually identified with a "purely" cognitive factor. This factor, labeled differently by different theorists (e.g., Bernyer, 1958; Horn, 1968; Vernon, 1965), may be interpreted at its most general level as involving the ability for spatial thinking and reasoning and general perceptual mastery. This hypothesis may seem more justifiable after examining the data on visual/spatial tasks and then analyzing the specific task requirements of the referential communication and recursive thought measures.

Further Consideration of Visual/Spatial Egocentrism Measures and Their Correlates

Several researchers have carefully analyzed the specific kinds of errors made by children on visual/spatial egocentrism measures, and one may refer to these for a more complete understanding of performance on these tasks (e.g., Coie et al., 1973; Eliot & Dayton, 1976; Fishbein et al., 1972; Huttenlocher & Presson, 1973; Shantz & Watson, 1971). The important point for this analysis is that in general, the proportion of egocentric errors is small at all ages, and the major developmental trend is not a tendency to make proportionately fewer egocentric errors but rather simply to make fewer errors of all kinds. Eliot and Dayton (1976), using a sample of 410 first graders, 421 fifth graders, and 260 adults and an adaptation of the three-mountains problem, found that egocentric (frontal) errors were made for the 90°, 180°, and 270° positions on only 16% of the trials with first graders and 8% of the trials with fifth graders. These proportions are not significantly different from each other. There was a highly significant decrease in the actual number of total errors made, however, and as expected, adults were proficient on this task. The authors concluded that young children are less perceptually accurate but not more perceptually egocentric.

Coie et al. (1973) found a similar tendency for egocentric errors to be relatively infrequent in a sample of 90 second, third, and fourth graders, although performance was far from perfect: Errors totaled 476, but only 80 of these were egocentric errors. They analyzed their data by ability levels (defined by performance on the egocentrism task) and did find a moderately significant trend towards making fewer egocentric errors at higher ability levels. Although this is more compatible with the observations reported by Piaget and Inhelder (1956) and Shantz and Watson (1971), these age or ability trends are easily overestimated. Coie et al. (1973) found that 20% of the errors in their lowest ability group were egocentric, which compares to a chance level of 8%. The authors concluded that development in this domain can best be characterized by small, undramatic transitions in the mastery of one's visual field.

A study even more striking in its demonstration of the small role played by egocentrism in the development of visual/spatial perspective-taking ability is a study by Fishbein et al. (1972). These researchers used a set of displays of increasing complexity briefly described in the last section (one or three toys and turning the display vs. pointing to one of either four or eight photographs). The complexity of the display and the mode of responding had significant effects on task performance, but the proportion of

egocentric errors did not show any tendency to decline with age. In fact, on the pointing task, preschoolers were less likely to make egocentric errors than were first graders across all variations of the display, even though the preschoolers made more total errors. Similarly, third graders were at least as likely as first graders to make egocentric errors. Together, these studies suggest that little of the variance in visual/spatial perspective-taking tasks can be attributed to egocentrism and that a straightforward cognitive reinterpretation might be tenable. Unfortunately, no study has related performance on visual/spatial tasks with scores on psychometric tests of spatial or perceptual thinking or with measures of spatial or perceptual processes such as mental rotation; consequently, this hypothesis requires further testing before confident conclusions can be drawn.

How do referential communication and recursive thought measures fit into this picture? A speculative hypothesis based on a simple analysis of the requirements of these tasks is that a major component of successful performance may be the ability to perceptually encode and discriminate the task stimuli. Referential communication measures such as that created by Glucksberg and Krauss (and used by Rubin in his 1973 study) use stimuli that are novel and difficult for children to perceptually process. The cognitive interpretation advanced here is supported by findings reported in Glucksberg et al. (1966). Up to age 4 (younger than Rubin's subjects) children were unable to successfully perform the task, even when pictures of familiar animals were substituted for the novel forms. However, between 52 and 63 months of age, all subjects could do the task with animals used as stimuli, but none could do it with the novel forms. Older subjects were not tested in this study, but another study by Hoy (1975) extends these observations of gradual improvement with age depending on the perceptual complexity and familiarity of the stimuli used as referents and nonreferents. Using 36 children aged 5, 7, and 9, Hoy found that children of all ages were better able to describe how to build a toy horse than they were a random shape and that performance improved with age for both stimuli. Similarly, Grushcow and Gauthier (1971) reported that 24 5-year-olds were more successful on a referential communication task using familiar rather than unfamiliar animals (67% vs. 46%) but were also more successful when unfamiliar animals were used than when familiar symbols were used (46% vs. 33%). When the task stimuli are chosen such that they are familiar and easily discriminable, children as young as 3 years old demonstrate an appreciation for the perspective of another: Maratsos (1973) found that children at this age were far more explicit verbally when communicating about the characteristics of simple referents (familiar toys) to an experimenter who apparently could not see than to an experimenter who could see.

In the recursive thought task, although subjects are taught to discriminate thinking cartoon clouds from talking clouds, most items are unusual and fairly complex perceptually. For example, if a boy is thinking of a girl who is thinking of the mother, three progressively smaller drawings of three different people appear in clouds of various shapes and sizes embedded in each other. Items of greater complexity may be even more difficult to decipher perceptually.

One important implication of this discussion is that although an awareness that others can have a different perspective and that one must infer that this perspective does seem to be required in most egocentrism measures, these abilities may be present in their simplest forms early developmentally (Borke, 1972). Although inferring perspective-taking ability is difficult in some egocentrism measures, presumably nonegocentric performance has been observed for children as young as 2 years old in the visual/spatial domain (Verkozen, 1975) and 3 years old in the affective (Borke, 1971) and cognitive/communicative domains (Maratsos, 1973; Menig-Peterson, 1975).

The implication of these findings for determining the sources of variance in performance on egocentrism tasks is that perspective-taking ability may account for little of the variance after age 4 or 5 (Mossler, Marvin, & Greenberg, 1976). More plausible sources of variance include (a) general intelligence

(Rubin, 1973); (b) verbal comprehension (Shantz & Watson, 1971); (c) specific cognitive factors such as spatial or perceptual abilities, depending on the complexity and/or familiarity of the task stimuli (Coie et al., 1973; Eliot & Dayton, 1976; Pufall, 1975); (d) characteristics specific to the type of response required (e.g., verbal vs. nonverbal; symbolic vs. concrete), since it may be the case that young children are unable to express their knowledge through the required response mode (Fishbein et al., 1972; Garber, 1975; Shantz, 1975); and (e) variables highly specific to the task, such as whether a real person or a doll is sitting in the position in which a visual/spatial perspective must be inferred, which Cox (1975) found made a significant difference (easier if a real person is used).

Summary. To summarize the data in this section and the implications of these data, visual/spatial, affective, and cognitive/communicative perspective-taking measures do not appear to tap a single unitary dimension of egocentrism. Measures of egocentrism are typically as highly correlated with other constructs (i.e., IQ, conservation, and popularity) as they are with measures of the same construct. Social speech and private speech measures may be tapping some common dimension that represents the developing child's mastery of language skills. Feffer's RTT and the measures of game strategy inference and awareness of privileged information seem to be independent of other measures in these domains, at least beyond any commonality due to general intelligence. For the most part, the same can be said for measures of affective egocentrism. This does not necessarily mean that these tests aren't measuring something that is consistent and important, since measurement reliabilities are generally adequate.

Visual/spatial, referential communication, and recursive thought measures seem to share some modest but significant amount of variance in addition to that attributable to general intelligence. Given that most errors made on visual/spatial perspective-taking tasks are not egocentric errors and that developmental improvements on these tasks are not characterized by dramatically smaller proportions of egocentric errors, the relationships among these three measures are more likely due to some common factor other than egocentrism, such as perceptual and/or spatial facility. For all of the measures that purport to measure egocentrism, task-specific and response-specific characteristics may account for a large proportion of the variance in performance, although this variance should not necessarily be construed as error, particularly if this variance can contribute to our knowledge about social cognitive development.

Conclusion

As a whole, the evidence reviewed in the last two sections and summarized in Tables 1–3 fails to support the construct validity of egocentrism. The most common finding is a lack of relationship among egocentrism measures, even for those whose reliability indicates that something consistent is being measured. The few commonalities found among specific tasks are more parsimoniously interpreted as the result of other explanatory constructs, such as those referring to the general level of cognitive, perceptual, or linguistic development of the child. Cronbach and Meehl (1955) comment that

> one who claims that his test reflects a construct cannot maintain his claim in the face of recurrent negative results because these results show that his construct is too loosely defined to yield verifiable inferences. (p. 291)

This statement is applicable to the research on egocentrism.

There are two main implications of negative evidence for construct validity. Either some or all of the tests are not good measures of the construct, or the theory that specifies the meaning of the construct is incorrect (Cronbach & Meehl, 1955). Since many of the egocentrism measures are reliable and possess a good deal of face validity, some doubt is cast on Piaget's theory, or at least that part of it that sets forth the meaning of egocentrism. Developing and testing alternative theoretical formulations that could better account for egocentric behavior is an investment of research effort that would most likely provide greater payoff in explanatory power.

Large Contingency Tables With Large Cell Frequencies: A Model Search Algorithm and Alternative Measures of Fit

Douglas A. Zahn
Department of Statistics, Florida State University and Harvard University

Sara Beck Fein
Research for Social Change, Washington, D. C.

A new search algorithm, the Generalized Guided Method, for locating a model for contingency tables and a measure of fit related to the R^2 of multiple regression are proposed for the analysis of contingency tables with many cells and large cell frequencies. This algorithm is designed to analyze contingency tables that contain dichotomous and/or nondichotomous (polytomous) variables. A $4 \times 2 \times 15 \times 7 \times 2$ contingency table with 559,158 observations is used for illustration.

The user of conventional multidimensional contingency table techniques, such as those described by Goodman (1972a, 1972b), encounters two problems in the analysis of contingency tables with many cells and with large cell frequencies: (a) which measures of fit to use in assessing and comparing models and (b) how to search for appropriate models among the multitude of possible hierarchical models. This article, building primarily on the work of Goodman, addresses these problems. A model selection criterion and a measure of fit that is less dependent on sample size than the traditional chi-square measures are proposed, and a new search algorithm for locating models that satisfactorily fit large contingency tables is described.

The data used for illustration are from Miller, Simons, and Fein (1974) and involve characteristics of 559,158 persons admitted to British mental hospitals. Miller et al. were interested in whether the legal code under which a person is admitted to the hospital varies by age (four age categories), sex (two sexes), region (15 regions), and year of admission (7 years). The two categories of the variable Legal Code are formal (similar to involuntary commitment) and informal (similar to voluntary commitment).

Requests for reprints should be sent to Douglas A. Zahn, Department of Statistics, Florida State University, Tallahassee, Florida 32306.

Notation and Terminology

The symbols A, S, R, Y, and L denote the variables in the five-way, $4 \times 2 \times 15 \times 7 \times 2$ contingency table under consideration: age, sex, region, year, and legal code, respectively. Let $f_{ijk\ell m}$ denote the observed frequency in cell (i, j, k, ℓ, m). Let $F_{ijk\ell m}$ denote the expected value of this cell under the model being fitted, and let $\hat{F}_{ijk\ell m}$ denote the estimate of $F_{ijk\ell m}$. F and $\hat{F}$ may be superscripted to indicate a specific model.

Attention is restricted here to the situation in which one of the dichotomous variables in the contingency table is viewed as a dependent variable. These techniques may also be used in situations with polytomous dependent variables, although the results are more difficult to interpret, as explained in Goodman (1971). Considering L as the dependent variable, let $\omega_{ijk\ell} = f_{ijk\ell 1}/f_{ijk\ell 2}$ denote the observed odds in favor of formal admission for patients in cell (i, j, k, ℓ). Let $\Omega_{ijk\ell}$ denote the expected odds that the admission is formal under the model being considered, where $\Omega_{ijk\ell} = F_{ijk\ell 1}/F_{ijk\ell 2}$. Let $\Phi_{ijk\ell} = ln\, \Omega_{ijk\ell}$, where ln denotes the natural logarithm. Thus Φ denotes the logarithm of the expected odds that an

admission is formal and has been termed by Bishop, Fienberg, and Holland (1975) and others the logit pertaining to variable L. The saturated model for Φ_{ijkl} can be written

$$\Phi_{ijkl} = \beta + \beta_i^{A} + \beta_j^{S} + \beta_k^{R} + \beta_l^{Y} + \beta_{ij}^{AS} + \beta_{ik}^{AR} + \beta_{il}^{AY} + \beta_{jk}^{SR} + \beta_{jl}^{SY} + \beta_{kl}^{RY} + \beta_{ijk}^{ASR} + \beta_{ijl}^{ASY} + \beta_{ikl}^{ARY} + \beta_{jkl}^{SRY} + \beta_{ijkl}^{ASRY}, \quad (1)$$

where the βs satisfy the constraints

$$\sum_{i=1}^{4} \beta_i^{A} = 0, \ldots, \sum_{i=1}^{4} \beta_{ijkl}^{ASRY} = \sum_{j=1}^{2} \beta_{ijkl}^{ASRY} = \sum_{k=1}^{15} \beta_{ijkl}^{ASRY} = \sum_{l=1}^{7} \beta_{ijkl}^{ASRY} = 0. \quad (2)$$

The order of an effect in the logit model is the number of letters in its superscript. An effect may be denoted by the letters in its superscript; for example, AS may be used to denote β_{ij}^{AS}. One effect is said to be a lower order relative of a second effect if the letters in the superscript of the first are a subset of those in the superscript of the second. Thus the third-order effects ASR and ASY are lower order relatives of the fourth-order effect ASRY. A hierarchical model is one in which, for each interaction appearing in the model, all lower order relative effects are also in the model.

Attention is restricted here to hierarchical models. Goodman's (1972b) "minimal set of marginal tables fitted under the model" (p. 39) notation will be used to denote the models that are considered. However, this notation presents a problem, since it refers to cell frequency models, that is, to models for $ln\, F_{ijklm}$ rather than to logit models, such as the one given in Equation 1. The difficulty can be circumvented by determining for each logit model its equivalent cell frequency model. A cell frequency model and a logit model are said to be equivalent if estimates of the parameters of the logit model that use the estimated cell frequency model parameters are equal to those produced by direct estimation of the logit model parameters. Since in logit analyses the contingency table formed by the independent variables is assumed to be fixed, the equivalent cell frequency models must preserve this table (see Goodman, 1971). Where L is the dependent variable, the cell frequency models that are equivalent to the logit models being fitted must preserve the (ASRY) margin. Using Goodman's techniques and notation, it can be shown that the cell frequency model that is equivalent to the logit model

$$\Phi_{ijkl} = \beta + \beta_i^{A} + \beta_j^{S} + \beta_k^{R} + \beta_{ik}^{AR} \quad (3)$$

preserves the (ASRY), (SL), and (ARL) margins. This model can be identified by the abbreviated list of β parameters included in it, that is, the parameters that have no higher order relatives in this logit model, namely S and AR.

Another aspect of the equivalence of cell frequency and logit models is that they yield the same estimated cell frequencies, $\hat{F}$. Using the estimated logits, $\hat{\Phi}_{ijkl}$ and the entries in the (ASRY) margin, $f_{ijkl+} = f_{ijkl1} + f_{ijkl2}$, one can compute estimated cell frequencies using the relation

$$\hat{F}_{ijkl1} = (f_{ijkl+}) \exp(\hat{\Phi}_{ijkl}) / [1 + \exp(\hat{\Phi}_{ijkl})], \quad (4)$$

where $\exp(x) = e^x$. Also, the $\hat{F}$s from the cell frequency model can be used to compute estimated logits that are equivalent to those obtained using the logit models, by the formula $\hat{\Phi}_{ijkl} = ln\,(\hat{F}_{ijkl1}/\hat{F}_{ijkl2})$. Since the $\hat{F}$s produced by logit models are equivalent to those produced by cell frequency models, the fit of a logit model may be assessed by the likelihood-ratio chi-square goodness-of-fit statistic for the equivalent cell frequency model.

Model A is said to be nested in Model B if Model A is a special case of Model B that can be obtained by setting some parameter(s) in Model B equal to zero. For example, the model (ARL), (ASRY) is nested in the model (ASL), (ARL), (ASRY).

Measures of Fit for Contingency Tables With Large Cell Frequencies

The hypothesis H that a specific model fits the data in a contingency table is examined by first determining the maximum likelihood estimates, assuming H is true, of the expected cell frequencies in the table, by using the iterative proportional fitting procedure, which is also called the Deming-Stephan (1940) algorithm. This can be done with any of several

contingency table computer programs that are available (e.g., Dixon, 1975; Goodman, 1973; Haberman, 1972; Zahn, Note 1). The use of this algorithm is illustrated in several articles, including those by Davis (1974), Fienberg (1970), and Goodman (1972a). Conventionally, the differences between the observed cell frequencies f_{ijklm} and the estimated expected cell frequencies $\hat{F}_{ijklm}$ under hypothesis H are examined to determine if the discrepancies are large enough to cast doubt on the hypothesis that H fits the data, by using the likelihood ratio chi-square statistic

$$\chi^2(\mathrm{H}) = 2\sum_i \sum_j \sum_k \sum_l \sum_m [f_{ijklm} \times ln\,(f_{ijklm}/\hat{F}_{ijklm})]. \quad (5)$$

This statistic has an asymptotic chi-square distribution with degrees of freedom denoted $df(\mathrm{H})$. (For an extended discussion of the calculation of $df(\mathrm{H})$, see Bishop et al., 1975, section 3.8; and Davis, 1974, pp. 205–208, 213). The computer programs listed above provide $df(\mathrm{H})$.

Problems arise if $\chi^2(\mathrm{H})$ is used as a measure of fit in a contingency table with large cell frequencies. Bishop et al. (1975, section 9.6) show that the magnitude of this statistic is proportional to the sample size if the hypothesis H is not exactly true. With large cell frequencies, only the saturated model may yield an insignificant chi-square statistic. Terms of marginal utility may be incorporated into the final model simply because their chi-square statistics are inflated to significance by the large sample size. This sacrifices the parsimony often desired in describing a data set. In addition, analysis of models that contain terms that have small effects may yield less accurate cell frequency estimates than does analysis of simpler models (Bishop et al., 1975, section 9.2; see Hocking, 1976, for analogous multiple regression results). These arguments also speak against the suggestion that with a very large sample size, the only appropriate analysis, rather than hypothesis testing, is the estimation of parameters in the saturated model.

In developing an alternative to chi-square for assessing the goodness of fit of a model, the assessment of fit of multiple regression models, which has been more extensively studied, should be considered. Namboodiri, Carter, and Blalock (1975, p. 458), in a discussion of models based on regression methods, suggest that the researcher not rely solely on tests of significance in assessing fit (a) because large sample sizes would lead to rejecting models with adequate fit and (b) because in the social sciences, even with a perfect model, measurement errors in the variables may produce distortions great enough to cause the model to be rejected. Among the suggestions by Draper and Smith (1966, pp. 165, 238) for assessing fit are (a) the subjective examination of the increase in R^2 as additional variables are added, looking for "breaks" in the rate of increase, after which additional variables add little explanatory power; (b) the setting of an arbitrary proportion of the total variance that must be explained for the model to be considered adequate. In their example, an R^2 of .80 is selected. There is, then, precedence for moving away from tests of significance as criteria of fit in the development of models.

Both of Draper and Smith's (1966) suggestions for alternative measures of fit are based on the assessment of the proportion of variation explained by the model. Goodman (1971, p. 54; 1972a, p. 1057) proposed a statistic analogous to the R^2 of multiple regression for contingency tables. He defined the statistic

$$R^2 = [\chi^2(\mathrm{H}_0) - \chi^2(\mathrm{H})]/\chi^2(\mathrm{H}_0), \quad (6)$$

where H_0 denotes the hypothesis $\Phi_{ijkl} = \beta$, that is, that the logits are constant, and therefore the effects of all variables in the logit model are zero.

The just defined R^2 statistic simultaneously reflects two pieces of information about Model H: (a) R^2 itself measures the proportion of the total variation in the table, as indicated by the lack of fit for Model H_0, $\chi^2(\mathrm{H}_0)$, which is explained by Model H; and (b) $1 - R^2$ measures the proportion of variation still unexplained in the table. This partition relates to the two chi-square statistics that are of interest in assessing any contingency table model. The first is the difference $\chi^2(\mathrm{H}_0) - \chi^2(\mathrm{H})$, which tests the significance of the parameters in Model H, whereas the second, $\chi^2(\mathrm{H})$, tests the

lack of fit of Model H or the significance of the parameters in the saturated model that are not in Model H. The first of these is analogous to the multiple regression F test of the hypothesis that all the parameters in the regression model are equal to zero, whereas the second statistic does not have an analogue in multiple regression, since in the latter context we do not have a test statistic available for the determination of whether the variance unexplained is statistically significant.

Our use of R^2 goes beyond Goodman's (1972a) recommendation that this statistic be used as a measure of how well Model H fits the data. We propose that R^2 may be a better criterion for choosing among models for contingency tables with large cell counts than is chi-square.

Comments on R^2

Perhaps the most difficult question relating to the use of R^2 as an indicator of the fit of a given model is when a model can be said to fit adequately. If the researcher were depending on statistical significance as a criterion, a cutoff point could be chosen, though the choice of a specific significance level is difficult. Even in multiple regression models, which have a longer history of usage, traditional cutoff points for the adequacy of R^2 have not been developed. Also, recent work in multiple regression indicates that judging when a multiple regression equation fits adequately may be a more difficult question than previously thought (Mosteller & Tukey, 1977, chap. 12–16). An additional problem in contingency tables is that researchers have considerably less experience in determining R^2 values of the kind proposed here than they do for multiple regression studies.

In general, the choice encountered in adding more parameters is between increased explanation of variation, that is, increased R^2, and increased complexity of the model. Results in the regression literature, as summarized by Hocking (1976), imply that the more interactions with small effects there are in the model, the less precisely the logits are estimated. As parameters are added to the model, generally the rate of increase in R^2 per parameter added decreases rapidly. Thus there comes a point in most contingency table analyses at which additional increments in the R^2 statistic will cost dearly.

Perhaps initial insight into the question of adequate magnitudes of R^2 can be developed by an examination of Table 1, which reflects the magnitudes of R^2 statistics evident in contingency tables fitted in the literature using conventional criteria. Note that the R^2 values for models with statistically insignificant chi-square statistics range from .796 to .9996.

Table 1
Sample Size, Degrees of Freedom, χ^2*, and* R^2 *Values for Models That Were Assessed in Recent Literature as Fitting Contingency Tables*

Source	n	df	χ^2	R^2
Goodman (1971)	1,008	8	5.66	.827
Goodman (1972b)	8,036	2	1.32	.9996
Goodman (1973)				
Model 8	2,982	2	.31	.995
Model 16	2,982	10	6.11	.911
Model 20	2,982	14	13.95	.796

Additional Alternatives to Chi-Square

A number of alternatives to chi-square, other than R^2, have been proposed for assessing fit of contingency table models. One of these is χ^2/N, where N denotes the total number of counts in the contingency table. This statistic enables the researcher to compare the lack of fit of various models, either from the same or different tables. The statistic R^2 can also be used to do this, and in addition, it measures how much improvement the current model offers over H_0.

A second alternative measure of fit is the correlation between the actual type of admission for a subject and the predicted probability of formal admission. The models for $\Phi_{ijk\ell}$ can be used to predict probabilities of formal admission. The predicted probability of formal admission for subjects in cell (i, j, k, ℓ) under the model being fitted is

$$\exp(\hat{\Phi}_{ijk\ell})/[1 + \exp(\hat{\Phi}_{ijk\ell})] = \hat{F}_{ijk\ell 1}/(\hat{F}_{ijk\ell 1} + \hat{F}_{ijk\ell 2}). \quad (7)$$

However, the correlation between a dichotomous variable and a predicted probability may

well be small under reasonable models, as demonstrated by Morrison (1972), although Goldberger (1973) has indicated that such a correlation can reach the bound of +1.0.

Another potential measure of fit reflects the fact that $R^2 = 1$ does not indicate that the model predicts perfectly whether an individual has a formal or informal admission; what is perfectly predicted is the proportion of formal admissions for individuals in cell (i, j, k, ℓ) for all such cells. Hence, another possible measure of fit is the proportion of subjects correctly classified as formal or informal admissions.

The measure of fit that is appropriate depends on the objectives of the research study. However, the consequences of using the different measures of fit and which measure is best in what circumstances appear to be open questions.

Generalized Guided Method for Locating Models for Large Contingency Tables

The saturated logit model for the $4 \times 2 \times 15 \times 7 \times 2$ contingency table that is used as an example in this article illustrates one of the problems encountered with large contingency tables: the number of linearly independent parameters in the model is 840, far too many to interpret easily. Since the saturated logit model will always fit the data perfectly, whether a satisfactory fit can be obtained using a simpler model is a matter of importance. With a large contingency table, it is important to have a computationally feasible plan for searching among the multitude of possible models. With only four independent variables, there are 166 possible models. Several algorithms have been proposed for finding an adequate model (Bishop et al., 1975, Fienberg, 1970; Goodman, 1973; Shaffer, 1973).

The first step of Goodman's guided method is to compute the standardized effect estimates, which are used to construct a series of nested models. A major problem with this method is that the magnitude of an effect cannot be measured by a single effect estimate unless all variables in the effect are dichotomous. For example, there are 420 parameters in the Legal Code $\times$ Age $\times$ Region $\times$ Year effect. This makes it virtually impossible to use Goodman's procedure to determine the order of entry of the effects. One reason for developing the method described below is to provide a procedure for summarizing the relative importance of the various effects in an interpretable way.

Shaffer (1973) suggests an approach for the determination of which parameters are important, but her approach is not feasible when large tables are analyzed. Fienberg's (1970) procedure is based on a posited series of nested hierarchical models but requires that the contingency table be well enough understood to construct the series of models before examining the data.

Bishop et al. (1975, section 4.5) discuss several search algorithms and emphasize that the strategy used should be sensitive to the specific research problem. The algorithm proposed here uses some of their recommendations, deletes others that in our experience have not been practical in consulting problems that involve contingency tables, and includes additional modifications we have found useful.

Higgins and Koch (1977) describe another approach to the analysis of large contingency tables that uses Pearson chi-square statistics, Mantel-Haenszel statistics, and the model-fitting procedure developed by Grizzle, Starmer, and Koch (1969). Benedetti and Brown (1978) also discuss several search algorithms. They stress the importance of examining each effect in the model, as is done in the algorithm described below, which is similar to the algorithm they propose.

Our search for a solution to the problems noted in previous methods has led us to develop the Generalized Guided Method (GGM), patterned after a method recommended for locating regression models when the number of independent variables is large. In these situations, some authors (e.g., Daniel & Wood, 1971) have recommended fitting a regression model by using all available variables and computing the partial F statistics for all variables in the model. For a given variable, the numerator of this statistic is the sum of squares explained by that variable after all other variables have been entered into the model. This is almost always a conservative measure of the explanatory power of this variable, since generally, if this variable were not the last to enter, it would explain more

variation. In searching for the final model in these regression situations, attention is focused on those variables with the largest partial F statistics.

In the first step of the GGM, the researcher computes a conservative measure of the explanatory power of each effect being considered for inclusion in the model. This measure is based on the reduction in the chi-square statistic due to adding that effect to the model after as many effects as possible (preserving the hierarchical nature of the model) have been included. Computation of this measure requires fitting a pair of models, denoted H* and H**, for each effect. The first model, H*, excludes only the effect of interest, denoted β^*, and its higher order relatives; it includes all other effects. Model H** includes the effects in H* and the effect of interest. Thus $\chi^2(\mathrm{H}^*) - \chi^2(\mathrm{H}^{**})$ can be used to test the hypothesis that the effect of interest is equal to zero, when as many effects as possible are entered into the model before it (cf. Goodman, 1972a, pp. 1051–1052).

For example, for the effect β_{ij}^{AS}, Models H* and H** are, respectively,

$$\Phi_{ijk\ell}=\beta+\beta_i^{\mathrm{A}}+\beta_j^{\mathrm{S}}+\beta_k^{\mathrm{R}}+\beta_\ell^{\mathrm{Y}}+\beta_{ik}^{\mathrm{AR}}+\beta_{i\ell}^{\mathrm{AY}} +\beta_{jk}^{\mathrm{SR}}+\beta_{j\ell}^{\mathrm{SY}}+\beta_{k\ell}^{\mathrm{RY}}+\beta_{ik\ell}^{\mathrm{ARY}}+\beta_{jk\ell}^{\mathrm{SRY}},$$

and

$$\Phi_{ijk\ell}=\beta+\beta_i^{\mathrm{A}}+\beta_j^{\mathrm{S}}+\beta_k^{\mathrm{R}}+\beta_\ell^{\mathrm{Y}}+\beta_{ij}^{\mathrm{AS}}+\beta_{ik}^{\mathrm{AR}} +\beta_{i\ell}^{\mathrm{AY}}+\beta_{jk}^{\mathrm{SR}}+\beta_{j\ell}^{\mathrm{SY}}+\beta_{k\ell}^{\mathrm{RY}}+\beta_{ik\ell}^{\mathrm{ARY}}+\beta_{jk\ell}^{\mathrm{SRY}}. \quad (8)$$

Thus this measure of the explanatory power of β_{ij}^{AS} is $\chi^2(\mathrm{H}^*)-\chi^2(\mathrm{H}^{**})=1{,}014.37-420.88=583.49$.

The difference $\chi^2(\mathrm{H}^*) - \chi^2(\mathrm{H}^{**})$ gives a misleading ranking of effects, since the numbers of linearly independent parameters associated with the effects are unequal. To adjust for this, the statistic $C(\beta^*)$ is used in the first step of the GGM to order the effects according to their explanatory power per linearly independent parameter, where

$$C(\beta^*) = [\chi^2(\mathrm{H}^*) - \chi^2(\mathrm{H}^{**})]/ [df(\mathrm{H}^*) - df(\mathrm{H}^{**})]. \quad (9)$$

For the effect β^{AS}, we obtain $C(\beta_{ij}^{\mathrm{AS}}) = (1{,}014.37 - 420.88)/(315 - 312) = 194.50$. Thus if effect β_{ij}^{AS} is added to the Model H*, the lack of fit is reduced by 194.50 per linearly independent parameter added. The addition of the effect β_{ij}^{AS} to the model actually

Note. This series is derived from results in Table 2.

involves including eight more parameters, three of which are linearly independent.

The results obtained in the first step of the GGM for our example are presented in Table 2. This step involves fitting 25 separate models.

In the second step of the GGM, a series of hierarchical models is constructed, starting with H_0 and adding effects one at a time in the order of the $C(\beta)$ statistics. The order of entry of the effects into the series of models is indicated in the last column of Table 2. For our example, this step produced the series of 12 unsaturated models listed in Table 3.

The third step in the algorithm is to fit the 12 models in the series. The results are presented in Table 3. At this point in the process, the researcher may use several strategies to select a reasonable model. We suggest that the researcher consider the following criteria (cf. Draper & Smith, 1966, pp. 165, 458): (a) The R^2 statistics in the series of nested models might be examined for "breaks," or points at which further increases in R^2 require a large number of additional parameters, and/or points at which the R^2 values level off. Using this criterion, either Model H_6 or Model H_{10} might be chosen from Table 3. (b) The researcher might decide what proportion of the total variation in the logits in the table must be explained for a model to be deemed adequate. Let R_T^2 denote this proportion. Then the simplest model H_u in the nested series in which $R^2 \geq R_T^2$ is identified. Model H_u and all other models in which $R^2 \geq R_T^2$ will be said to be "R_T^2 adequate."

A goal of $R_T^2 = .80$ has been chosen here. An examination of Table 3 indicates that $H_u = H_6$; that is, H_6 is the simplest model in the nested series that is .80 adequate. We note that there are other models for this table that are .80 adequate, including $H_7, H_8, \ldots, H_{12}$. Unfortunately, identifying all .80-adequate models requires fitting many models to this contingency table. We recommend this step when it is computationally feasible. However, when the number of dimensions is large, this procedure is expensive; it is for these situations that the GGM is useful. We fitted all possible logit models to establish a standard for evaluating the GGM. This step located 40 models with $R^2 \geq .80$.

The fourth and final step of the GGM is to identify a minimal R^2_T-adequate model. Model H will be termed minimal R^2_T adequate (a) if $R^2(\mathrm{H}) \geq R^2_T$ and (b) if for any Model H′ that can be constructed by deleting one or more effects from H, preserving the hierarchical nature of the model, $R^2(\mathrm{H}') < R^2_T$. This criterion reduces the 40 models that are .80 adequate to the following three minimal .80-adequate models: (a) (ASRY), (ARL), (RYL), (AYL), (SYL); (b) (ASRY), (ARYL), (SL); (c) (ASRY), (ASL), (RYL), (ARL) (Model H_6).

For illustration, the calculations are presented in Table 4 for Model H_6 only, the model found through earlier steps of the GGM. These calculations indicate that the removal of any effect from Model H_6 yields $R^2 < .80$; hence, Model H_6 is minimal .80 adequate.

In summary, we note that the GGM located one of the three minimal .80-adequate models for this table. The selected model is

$$\text{Model } H_6: \Phi_{ijkl}=\beta+\beta_i^{A}+\beta_j^{S}+\beta_k^{R}+\beta_l^{Y}+\beta_{ij}^{AS}+\beta_{ik}^{AR}+\beta_{kl}^{RY}. \quad (10)$$

At this point, the researcher knows that no three-way interactions are necessary to explain at least 80% of the variation in the logits; with reasonable accuracy the odds ratio of the number of informal to the number of formal admissions for any cell in the Age × Sex × Region × Year four-way table of logits can be predicted using only the parameters indicated in Model H_6. Thus instead of having to contend with one four-dimensional table with 840 parameters, the researcher knows that three two-way tables, with 8, 60, and 105 parameters, summarize the most important interactions in the full four-way table. (For additional comments on interpretation, see Davis, 1974; and Goodman, 1972a, 1972b.)

Evaluating the GGM

It is reasonable to judge a model selection algorithm by checking to see whether it finds a good model. This necessitates defining a good model. Two possible criteria come to mind here, one relating to R^2 and the other to chi-square. The best .80-adequate model could be defined as that model with the minimum number of parameters that yields $R^2 \geq .80$. Alternatively, the best model may be the one that yields an insignificant chi-square with the minimum number of parameters in the model. We have examined the performance of the GGM, relative to these two criteria, on the five-way table used throughout this article and on the 2 × 2 × 2 × 2 table from Goodman (1972b).

For the five-way table, the GGM selected the best $R^2 = .80$ model, and for the 2 × 2 × 2 × 2 table, it selected the best $R^2 = .99$ and $R^2 = .999$ models. Also, for the 2 × 2 × 2 × 2 table, the GGM selected the best model that used the chi-square criterion and significance level of .01. The calculations required to apply the GGM to the 2 × 2 × 2 × 2 table are presented in Tables 5 and 6. Comparing the analysis using the GGM with Goodman's analysis, we note that depending on the value of R^2_T, the GGM will select either the model chosen by Goodman or a more parsimonious model that explains almost as much variation.

We emphasize that these investigations of the GGM are empirical investigations, and the results are based on the analyses of only two contingency tables. However, on the basis of these analyses, the GGM does appear to perform well. We emphasize that there will generally be more than one minimal adequate model for a table. Additional insight into the structure of the table may be gained by locat-

ing all minimal adequate models and comparing the alternative explanations offered by these models.

Discussion

The GGM is a flexible model selection procedure; it is not intended to be an automatic procedure into which the experimenter inserts a contingency table and an R_T^2 value and from which a model is received. Rather, it is proposed as a reasonable procedure for searching among the multitude of possible hierarchical models for appropriate models that satisfy specified criteria. If the researcher has little or no prior information, the procedure will help to identify reasonable models.

If, however, the researcher has additional information on the contingency table, the GGM can be modified to incorporate that information. For example, if it is known from previous studies that certain effects almost

Note. This series of models is derived from results in Table 5.

surely must be included in any model that is to fit the contingency table, then the model that includes those effects could be used as the base model for beginning the search, rather than Model H_0.

Another way that the GGM can be modified to reflect substantive knowledge that the researcher may have is that the choice among minimal adequate models need not necessarily center on the model with the fewest parameters. Given substantive considerations, it may be that one of the other minimal adequate models is far more interpretable or useful.

If the researcher prefers to use chi-square-based statistics rather than the R^2 statistics, the GGM can be easily modified to accomodate this. For example, the effects can be ordered by $\chi^2(H^*) - \chi^2(H^{**})$ rather than by $C(\beta)$.

The researcher may wish to restrict attention to models with no effect of order higher than some selected value, for example, three. If this is the case, then Step 1 in the GGM is easily modified to include an examination of only those effects that are candidates for inclusion in the model; no fourth or higher order effects would be examined in Step 1.

The GGM may also be based on an ordering of the effects by their contribution when each is entered as soon as possible into the model. In Step 1, instead of comparing H^* and H^{**} as defined earlier, the researcher would compare the Model H' that contains only the effect of interest and its lower order relatives, with the Model H'' containing all effects in H' except the effect of interest. For example, to obtain the contribution of AS, the Model H' [(ASRY), (AL), (SL), (ASL)] would be compared with H'' [(ASRY), (AL), (SL)]. We performed this procedure for the five-way table from Miller et al. (1974), which was used as an example in earlier sections, and for the table obtained from Goodman (1972b), which was analyzed in earlier sections. For the five-way table, the results were identical to those of the procedure in Step 1 of the GGM, which ordered the effects by their contribution when entered last into the model, except that the age and Age × Sex effects, which were close in value, were reversed. The two procedures yielded the same final model. In the analysis of the Goodman data, the two procedures yielded the same order of entry and the same final model. Thus the impact of a variable's order of entry on the ranking of its explanatory power appears to be much smaller here than is the case in multiple regression.

Only the class of nonhierarchical models is excluded from consideration by the GGM. Any hierarchical combination of main and higher order effects could be selected. Step 1 in the algorithm assures that all higher order effects will be examined. Thus important higher order interactions would not be missed, as they might be if we fit only models of uniform order, that is, models with all two-factor interactions, then models with all three-factor interactions, and so forth continuing until the lack of fit of a model of uniform order is insignificant.

The analyses described here are in the spirit of exploratory, rather than confirmatory, statistical analyses (Tukey, 1977); many tests are being performed on the same set of data after the fact. Hence, the significance probabilities obtained should be viewed as guidelines rather than as the results of formal tests.

In concluding, we advise, as do Bishop et al. (1975), that before a final decision on a model is made, the fit of the model should be examined cell by cell to check for outliers or any unusual patterns in the residuals.

Superior–Subordinate Communication: The State of the Art

Fredric M. Jablin
Department of Speech Communication, University of Texas at Austin

Based on a review of the literature, empirical research in the area of superior–subordinate communication is classified into nine topical categories and critically examined. Inspection of this literature suggests that researchers have focused the majority of their attention on studying (a) the effects of power and status on superior–subordinate communication, (b) trust as a moderator of superior–subordinate communication, and (c) semantic-information distance as a source of misunderstanding in superior–subordinate communication. It is concluded that future research should increasingly be developmental and longitudinal in nature and should take into greater consideration the effects situational variables have on communication in the superior–subordinate dyad.

Status hierarchy is inherent in the nature of purposeful organizations. As Redding (1972) observes, within organizations "there are 'superiors' and 'subordinates'—even though these terms may not be expressly used, and even though there may exist fluid arrangements whereby superior and subordinates roles may be reversible" (p. 18). How superiors and subordinates interact and communicate to achieve both personal and organizational goals has been an object of investigation by social scientists for most of the 20th century. Empirical research examining superior–subordinate communication is diverse, is strewn across a multitude of disciplines, lacks coherent organization and classification, and in general, has not received sufficient review and interpretation as a body of literature. The present article attempts to alleviate this confusion by reviewing, classifying, interpreting, and providing directions for future research in the area of organizational communication that is loosely termed *superior–subordinate communication*.

This article focuses on empirical research solely in the domain of organizational communication. To avoid generalizations from communication research outside of the organizational environment, I do not review investigations exploring small group and interpersonal communication extraneous of purposeful organizations (with occasional exception). Since organizational communication is different, in a variety of ways, from communication in other settings (e.g., Redding, 1972, Rogers & Rogers, 1976) and given the difficulty of generalizing from social science research, regardless of area, limiting the setting (or scope) certainly adds to the validity of any knowledge claims. For example, it is difficult to generalize from small group communication research, which is external to organizational environments, to group communication within organizations, in which groups of groups are tied together in networks of networks. Hence, this review focuses on studies conducted within organizations or simulations of organizations.

In addition, this collection and critique of superior–subordinate communication research has excluded studies related to interviewing, despite the fact that they may have involved superior–subordinate interaction. (See Daly, Note 1, for a complete review of this literature.) Moreover, the nucleus of this review is the examination of interpersonal dyadic interactions between superiors and subordinates. Specifically, an attempt was made to avoid examination of research concerned with the use of impersonal, media-related (e.g., house organ, bulletin board, suggestion box)

superior–subordinate communication. However, both written and oral face-to-face communication transactions, when of an interpersonal dyadic nature, were reviewed.

The article is organized into three sections; the first presents a basic definition of superior–subordinate communication. The second section reviews and organizes empirical research related to superior–subordinate communication into nine topical categories. The final section provides a discussion of the review and directions for future research.

Superior–Subordinate Communication Defined

The expressions superior and subordinate are derived from Latin roots, which when joined suggest that within an interpersonal relationship one individual is of subrank or is situated below another. In purposeful organizations, both formal and informal superior–subordinate relations usually exist. Moreover, most research evidence indicates that informal (i.e., not prescribed by organizational directives) superior–subordinate affiliations may be as important as formal veritable relations in determining communicative behavior. However, for the purposes of the present review, the definition of superior–subordinate communication is limited to those exchanges of information and influence between organizational members, at least one of whom has formal (as defined by official organizational sources) authority to direct and evaluate the activities of other organizational members.

Katz and Kahn (1966) provide probably the most parsimonious yet complete description of the types of communication that are typically exchanged in superior–subordinate interactions. These theorists suggest that downward communications from superior to subordinate are of five basic types: (a) job instructions, (b) job rationale, (c) organizational procedures and practices, (d) feedback about subordinate performance, and (e) indoctrination of goals (pp. 239–241). On the other hand, communication upward from subordinate to superior is reported to take four primary forms: (a) information about the subordinate himself/herself. (b) information about co-workers and their problems, (c) information about organizational practices and policies, and (d) information about what needs to be done and how it can be done (p. 245). More specific and detailed taxonomies of messages exchanged in superior–subordinate communication are available in the literature (e.g., Eilon, 1968; Melcher & Beller, 1967; Yoder, 1970).

Review of Literature

The empirical literature on superior–subordinate communication has been divided into nine topical categories.[1] Each of these categories represents a series of investigations that appear to be researching similar constructs from analogous theoretical foundations.[2] Many of the studies reviewed share more than one category but were classified into conceptually distinguishable groupings for purposes of clarification and parsimony.

Interaction Patterns and Related Attitudes

Researchers have investigated a variety of issues related to interaction patterns between superiors and subordinates. For example, numerous studies report that between one third and two thirds of a supervisor's time is spent in communicating with subordinates and that face-to-face discussion is the dominant mode of interaction (e.g., Berkowitz & Bennis, 1961; Brenner & Sigband, 1973; Dubin & Spray, 1964; Hinrichs, 1964; Kelly, 1964;

---

[1] The reader will note that this review contains no single category of research related to downward communication in superior–subordinate interaction. Since Redding (1972, see especially pp. 388–404) provides an extensive review of this literature prior to 1970 and given that less research has been pursued in this area subsequent to 1970, the present review has not directly focused attention on this area. Rather, research related to downward communication is discussed within the confines of the other categories.

[2] The reader will also note that this review does not consider research that could be classified as relating to participative decision making. Since exhaustive reviews of this literature already exist (e.g., Redding, 1972, pp. 154–250; Vroom, 1970, pp. 227–240; Vroom, 1976, pp. 1538–1546) further critique would be redundant.

Lawler, Porter, & Tenenbaum, 1968; Penfield, 1974). Moreover, results from a number of investigations indicate that the majority of superior–subordinate interaction concerns task issues (e.g., Baird, 1974; Richetto, 1969; Zima, 1969; Walton, Note 2) and that superiors and subordinates talk more about impersonal (focus of topics external to self) than about personal (directly related to self) topics (Baird, 1974). Further, research suggests that superiors are more likely to initiate interactions with subordinates than the other way around (e.g., Berkowitz & Bennis, 1961; Dubin & Spray, 1964). Yet, it is of interest to observe that superiors are less positive toward and less satisfied with interactions with their subordinates than they are with contacts with their bosses (e.g., Clement, 1974; Lawler et al., 1968; Tenenbaum, 1971). This finding is even more ironic when considered in light of Baird and Diebolt's (1976) discovery that a subordinate's job satisfaction is positively correlated with estimates of communication contact with superiors.

Several other studies present findings relevant to interaction patterns between superiors and subordinates. The results of these investigations suggest the following conclusions: (a) Superiors perceive that they communicate more with subordinates than subordinates perceive, whereas subordinates feel they send more messages to their superiors than the latter perceive (Webber, 1970); (b) superiors who lack self-confidence in their leadership abilities are less willing to hold face-to-face discussions with their subordinates than are superiors who are confident in their leadership abilities (Kipnis & Lane, 1962); (c) role conflict and role ambiguity are strongly correlated with "leader behavior indicative of direct as opposed to indirect interactions with subordinates" (Rizzo, House, & Lirtzmann, 1970, p. 162); (d) when a subordinate needs informal help in the work setting, he/she is more likely to seek assistance from his/her superior than peers or subordinates (as reported by helpees) (Burke, Weir, & Duncan, 1976); and (e) supervisors are more likely to serve as "production" communication liaisons than as "maintenance" or "innovation" liaisons (MacDonald, 1976).

In summary, studies that explored interaction patterns between superiors and subordinates suggest frequent task-oriented communication within the dyad but differential attitudes and perceptions of those interactions. Moreover, personal characteristics and needs of the interactants seem to mediate their desire for and perceptions of superior–subordinate communication.

Openness in Communication

Two basic dimensions of openness in superior–subordinate communication can be distinguished: openness in message sending and openness in message receiving. Redding (1972) describes openness in message sending as the "candid disclosure of feelings, or 'bad news,' and important company facts" (p. 330), whereas openness in message receiving involves "encouraging, or at least permitting, the frank expression of views divergent from one's own; the willingness to listen to 'bad news' or discomforting information" (p. 330). Baird (1974) adds that it is essential that researchers clearly specify whether they are referring to task-relevant openness or non-task-relevant openness when investigating each of the above dimensions.

Much of the impetus for studying openness in superior–subordinate communication has been provided by management theorists who have suggested that openness is an essential element for an effective organizational climate (e.g., Haney, 1967; Likert, 1967). Support for this proposition is furnished in studies by Burke and Wilcox (1969), Baird (1974), and Jablin (1978a), who have found that employees are more satisfied with their jobs when openness of communication exists between subordinate and superior. Furthermore, several inquiries report that openness of communication is directly correlated with organizational performance (e.g., Indik, Georgopoulos, & Seashore, 1961; Willits, 1967). However, it should be noted that the results of one investigation suggest that managerial effectiveness is unrelated to openness of communication between superior and subordinate (Rubin & Goldman, 1968).

A series of doctoral dissertations completed at Purdue University have attempted to ex-

plore in detail the communication characteristics of openness in superior–subordinate relationships. The first of these researches (Baird, 1974) examined subordinates' "upward communication freedom" with superiors. Results of the study revealed that willingness of superiors and subordinates to talk as well as actual talk about a topic is a function of each interactant's perception of the other's willingness to listen. Extrapolating on Baird's study, Stull (1975) investigated superior and subordinate attitudes toward various types of supervisory responses to task-relevant and non-task-relevant open messages sent by subordinates. Analyses disclosed that for task and nontask topics, subordinates and superiors preferred supervisory responses that were accepting (encouraging) or reciprocating ("owning-up" to one's feelings, ideas, etc.) rather than neutral-negative (unfeeling, cold, or nonaccepting). Finally Jablin (1978a, 1978b), attempting to determine the types of communicative responses that characterize open and closed relationships between superiors and subordinates, experimentally studied the attitudes of subordinates toward five basic types of message responses occurring in a dyad: confirmation (a response that provides a speaker with positive content and positive relational feedback), disagreement (a response that provides a speaker with negative content feedback but positive relational feedback), accedence (a response that provides a speaker with positive content feedback but negative relational feedback), repudiation (a response that provides a speaker with both negative content and negative relational feedback), and disconfirmation (a response that provides a speaker with irrelevant content and equally irrelevant relational feedback). Results from the investigation indicated (a) that disconfirming responses are not acceptable in superior–subordinate communication; (b) that subordinates prefer message responses from superiors that provide positive relational feedback; (c) that regardless of perceived openness or closedness of the communication relationship with their superior, subordinates expected the same types of responses from a superior but evaluated the appropriateness of these responses differently; (d) that a substantial degree of reciprocity exists for confirming messages, regardless of the openness or closedness of the superior–subordinate relationship; and (e) that subordinates who perceive a closed relationship with their superior are prepared to respond to a superiors' message, which contains negative relational feedback toward the subordinate, with a response transmitting negative relational feedback toward the superior; however, this is not true for subordinates who perceive an open relationship with their superior.

In summary, these studies suggest that in an open communication relationship between superior and subordinate, both parties perceive the other interactant as a willing and receptive listener and refrain from responses that might be perceived as providing negative relational or disconfirming feedback. Moreover, these inquiries suggest that what distinguishes an open from a closed superior–subordinate relationship may not be the types of messages exchanged but how the interactants evaluate the appropriateness of these communications. Finally, these studies provide strong evidence for the proposition that employees are more satisfied with their jobs when openness of communication exists between superior and subordinate than when the relationship is closed.

Upward Distortion

Closely related to research examining openness in superior–subordinate relationships are a group of investigations exploring message distortion in subordinate upward communication to superiors. Mellinger (1956), who collected questionnaire data from 330 scientists in a medical laboratory, is generally credited with the initiation of this research tradition. (For a discussion of related research antecedent to Mellinger's investigation, see Guetzkow, 1965, pp. 553–555.) Results of this early inquiry into message distortion revealed that when Individual A does not trust Individual B, Individual A will conceal his/her feelings when communicating to B about a particular issue. Moreover, concealment of Individual A's true feelings was found to be often associated with evasive, compliant, or aggressive communicative behavior on his/her

part and with under- or overestimation of agreement on the issue by Individual B. Cohen's (1958) replication and clarification of Kelly's (1951) investigation of upward communication in experimentally created hierarchies also inspired a tradition of research in the area of upward communication distortion. Results of this study suggested that within a hierarchy, if an individual has power over the advancement of persons of lower rank, those of lower rank will omit critical comments in their communication with the person of higher rank. Thus with these seminal studies, Mellinger (1956) and Cohen (1958) initiated a sphere of research that examined the moderating effects of trust and mobility aspirations on upward communication distortion.

Building on the previously described research, Read and his associates (Maier, Hoffman, & Read, 1963; Read, 1962) explored the relationships among upward mobility aspirations, trust, and the accuracy with which managers communicate information upward in organizational hierarchies. Data analyses supported the earlier findings of Mellinger and Cohen, which indicated that mobility aspirations (i.e., desire for advancement and status seeking proclivity) and low trust in one's superior are negatively related to accuracy of upward communication. Moreover, results suggested that even when a subordinate trusts his/her superior, high mobility aspirations "strongly militate against accurate communication of potentially threatening information" (Read, 1962, p. 13). In addition, it was discovered that "subordinates feel less free to communicate with superiors who previously have held their position than with those who have not" (Maier et al., 1963, p. 9).

More recently, research by Roberts and O'Reilly (1974) and O'Reilly and Roberts (1974) has supported the notion that a subordinate's trust in his/her superior is a facilitator of distortion-free upward communication. However, these researchers did not find strong correlations between subject's mobility aspirations and propensity towards upward communication distortion. Finally Sussman (1974), investigating upward communication distortion from the perspective of the superior (i.e., the recipient of distorted messages), failed to find that superiors perceive greater accuracy in messages from subordinates who are perceived as trusting the superior than in messages from subordinates perceived as nontrusting.

In contrast to these studies, several researchers have investigated the origins and concomitants of upward communication distortion from slightly different perspectives. Athanassiades (1973, 1974) argues that ascendency and security needs, risk-taking propensity, and organizational climate, when perceived as instrumental to a subordinate's goals, will produce upward communication distortion. Results of his research indicate that for both male and female subordinates, upward distortion is need motivated, with distortion being positively related to achievement needs and negatively related to level of security. Furthermore, Athanassiades's findings suggest that distortion of upward communication is negatively related to an autonomous organizational climate and positively related to a heteronomous climate. It is of interest to observe that his findings (1974) also show that "women in managerial positions feel more suppressed—less autonomous, less independent—than men do in similar positions" (p. 208).

A recent study by Young (1978) supports Athanassiades's finding that organizational climate is related to distortion of upward communication. Specifically, results suggest that in organic as compared with mechanistic organizational environments, subordinates perceive greater appropriateness, expect fewer harmful consequences, and evidence greater willingness to disclose important yet personally threatening information to superiors. However, his data also disclose that the upward communication behavior of female subordinates follows more closely the behavior of subordinates in an organic work setting than does the upward communication of male subordinates.

Extrapolating on Athanassiades's research, Level and Johnson (1978) have recently found that upward distortion is most likely to be associated with messages in which in-

formation about the following personality factors is communicated: ascendency, responsibility, emotional stability, cautiousness, and original thinking. Their data also suggest that in certain areas subordinate tendencies to distort upward communication can be reduced by increasing the superior's "consideration" leadership style, or increasing the accuracy with which the superior transmits downward information. In addition, Krivonos (1976) examined the role of motivation theory in upward communication distortion and found that superiors perceive that intrinsically motivated subordinates distort messages less than do extrinsically motivated subordinates.

Research that investigates types of messages that tend to be distorted in upward communication indicates that subordinates will be less reluctant to communicate information that is positive–favorable than negative–unfavorable (O'Reilly & Roberts, 1974; Rosen & Tesser, 1970) and that superiors view messages that are favorable to subordinates as less accurate than messages that are unfavorable to subordinates (Sussman, 1974). Moreover, O'Reilly and Roberts (1974) report that when information is both favorable and important, subordinates do not hesitate to communicate it upward to their superiors. In addition, Housel and Davis (1977) have discovered that subordinate satisfaction with upward communication tends to vary as a function of the channel used; face-to-face channels are most satisfactory, followed by telephone and written channels. Finally, a recent study of Rosen and Adams (1974), which examined the severity of discipline administered to subordinates who distorted upward communication, reveals that "recommended disciplinary measures were relatively mild when the subordinate's motives were altruistic and when his superior was dependent on him for expertise" (p. 382).

In summary, research that explored upward distortion in superior–subordinate communication has examined numerous variables that may moderate the occurrence of upward distortion. These variables include trust, mobility aspirations, ascendency and security needs, organizational climate, sex differences, motivation, message characteristics, and a variety of upward communication channels. Although the effects of subordinate trust in superior, subordinate mobility aspirations/ascendency needs, and the contingent role of organizational climate on upward distortion seem best supported, evaluation of the research in total suggests that probably no one variable can sufficiently explain the phenomena and that additional multivariate research is required before we can place confidence in any one of these explanations.

Upward Influence

Influence processes are a central feature of superior–subordinate communication. And, as Walter (1966) notes,

> to study influence, one must first study communication, for influence without communication is as wildly implausible as action at a distance. Influence is always accompanied by some form of communication, blunt or subtle, overt or tacit: Advertising, lobbying, arguing a case before a jury or on a suitor's knee. (p. 190)

In studies of superior–subordinate communication, researchers have focused attention on two basic dimensions of influence: (a) the effects a superior's influence in the organizational hierarchy has on his/her relationships with subordinates and (b) the transmission of influence by subordinates to superiors. Research in this latter category is diffused and varied, and since it is represented in other sections of this article (e.g., upward distortion, feedback), it is not directly discussed here.

Due to its effects on superior–subordinate relations, the upward influence of a subordinate's superior with his/her boss has received considerable attention in the research literature. Probably best known is the so-called "Pelz effect." In his seminal study Pelz (1952), who collected data from over 8,000 supervisory and nonsupervisory personnel in the Detriot Edison Company, discovered that a superior's upward influence in an organization moderates his/her social closeness with subordinates. Specifically, he found that "employee-centered supervisors are associated with higher levels of employee satisfaction *only when the supervisor apparently exercises influence 'upward' with his own superiors*"

(Redding, 1972, p. 438). More recently Wager (1965), who explored leadership behaviors and influence in one organization, reported findings similar to those of Pelz but also observed that the magnitude of the moderating effect of influence varied positively with the organizational status of the respondent. At this point it is important to note that Pelz's and Wager's influence measures were concerned only with supervisory influence with respect to personnel management of subordinates and did not assess influence in such areas as resource allocation, organizational changes, policy formation, or objective setting (Wager, 1965). Moreover, this typifies most of the research in this area.

In recent years investigators have once again begun to explore the relationship between superior's upward influence and communication with subordinates. For example, House, Filley, and Gujarati (1971) report that the interaction between superior's hierarchical influence and consideration behavior with subordinates varies from company to company (i.e., it is situational). Perhaps of even greater importance is their finding that when a superior is too high in upward influence, dysfunctional consequences may emerge in relation to subordinate willingness to openly communicate with the superior. They argue that

> where supervisors are seen to have such high influence, it is likely that there will be greater status separation between them and their subordinates, and that such status differentiation will result in a restriction of upward information flow, less willingness on the part of subordinates to approach superiors, and less satisfaction with the social climate of the work unit. (p. 429)

In a related study, Roberts and O'Reilly (1974) report that subordinates who perceive their superior as having high upward influence also have a high desire for interaction with the superior, high trust in the superior, and a high estimation of accuracy of information received from the superior. Similarly, Jones, James, and Bruni (1975) have found that subordinate confidence and trust in a superior is positively related to the superior's success in interactions with higher levels of management. Finally, O'Reilly and Roberts (1974) and Roberts and O'Reilly (1974), who examined the association between superior upward influence and subordinate upward communication distortion, have discovered only weak correlations between these variables.

In summary, results from studies that explored the relationship between superior's upward influence and communication with subordinates suggest the following conclusion: Subordinates who perceive their superior as having substantial but not excessive upward influence with their bosses will be more satisfied with their superior and will interact and trust him/her more than will subordinates who perceive their superior as low in upward influence. However, since several of the previously described investigations indicate that this conclusion may be situation bound and may be contingent on factors other than those already studied, the conclusion warrants only tentative acceptance.

Semantic-Information Distance

Originally coined by Tompkins (1962), the term *semantic-information distance* describes the gap in information and understanding that exists between superiors and subordinates (or other groups within an organization) on specified issues. This concept is analogous to the concept of "disparity" advanced by Browne and Neitzel (1952), to Weaver's (1958) construct of "semantic barrier," to "categorical and syndectic similarity" as proposed by Triandis (1959a, 1959b, 1959c, 1960), to "semantic agreement" as discussed in Maier, Hoffman, Hooven, and Read (1961) and Maier et al. (1963), and to "congruence" as explored in research by Minter (1969). Studies that examined the nature and definitional qualities of semantic-information distance through 1970 are discussed in detail in Redding's (1972) review of organizational communication literature.

The basic conclusions that can be drawn from the early research on semantic-information distance can be briefly described as follows: (a) The larger the semantic distance between superior and subordinate, the lower will be the subordinate's morale (Browne & Neitzel, 1952); (b) superiors tend to overestimate the amount of knowledge subordi-

nate's possess on given topics (Odiorne, 1954); (c) management personnel tend to describe themselves by traits that are different from those that subordinates use to describe themselves (Porter, 1958); (d) managers and workers differ in the criteria that they use in making judgments about people (Triandis, 1959a, 1959b, 1959c, 1960); (e) significant gaps in semantic distance exist between union and management (Schwartz, Stark, & Schiffman, 1970; Weaver, 1958) and between union leadership and their members (Tompkins, 1962); (f) superiors and subordinates have difficulty agreeing on the basic job duties and demands facing subordinates (Maier et al., 1961; Rosen, 1961); (g) whether a superior has previously held his/her subordinate's job has little effect on reducing the semantic-information distance between them (Maier et al., 1963); (h) superior's perceptions of the attitudes of subordinates toward him/her is often unrelated to their actual attitudes (Bowers, 1963; White, 1976); (i) serious semantic differences between superior and subordinate are frequent (e.g., Minter, 1969, reports that they occur over 60% of the time); and (j) there is some evidence that indicates that superiors "find it easier to communicate with subordinate managers whose attitudes are similar [rather than dissimilar] to their own" (Miles, 1964, p. 324).

In general, most research related to semantic-information distance conducted since 1970 is supportive of the aforementioned studies. Greene (1972) has found that the more accurately a subordinate complies with his/her superior's expectations of subordinate behavior, the higher the subordinate's job satisfaction and the better his/her performance evaluation by the superior. Supportive of the results of Greene's research is a study by Pfeffer and Salancik (1975) that suggests that the behavior of subordinates and superiors is constrained by the expectations of other members of the role set. Several recent investigations contribute to the list of areas in which significant superior–subordinate semantic-information distance exists. Examining superior–subordinate dyads, Boyd and Jensen (1972) found that first-line managers and their superiors experience difficulty in agreeing on the authority of the first-line manager, whereas Moore (1974) reports that a new manager's superior and his/her subordinates tend to disagree on how long it will take the manager to learn the new position. Assuming that empathic ability is negatively correlated to semantic-information distance, Northouse's (1977) study would strongly indicate that one means of reducing semantic distance is by increasing trust between superior and subordinate. Finally, a study by Baird and Diebolt (1976) found no relationships between superior–subordinate role congruence and several communication variables; however, limitations within the study restrict the generalizability of its findings.

In summary, results of empirical research in the area of superior–subordinate semantic-information distance probably provide some of the most consistent conclusions of any topic of study in organizational communication. Incessantly, we find the existence of semantic-information distance in superior–subordinate relations, often at levels that would appear to seriously obstruct organizational effectiveness. The catalogue of topical areas in which semantic differences between superiors and subordinates tend to occur is expanding and would strongly suggest that future research should pursue the development of valid and reliable techniques to reduce this semantic gap.

Effective Versus Ineffective Superiors

Interest in identifying the communicative behaviors of effective leaders probably has existed since the earliest days of civilization, when humankind became proficient at organizing for battlefield warfare and thus required an expendable supply of effective leaders. Hence, over the years the identification of effective as compared to ineffective communication behaviors of superiors has received more investigation than any other area of organizational communication.

From the period of 1950 to the mid-1960s, a series of doctoral dissertations completed at Purdue University attempted to determine the communication correlates of "good" supervisors (Funk, 1956; Kelly, 1963; Minter,

1969; Miraglia, 1964; Pyron, 1964; Richetto, 1969; Simons, 1962; Sincoff, 1970; Smith, 1968; Zima, 1969). For the majority of these studies, good supervision as compared to poor supervision was determined by higher management evaluation of supervisors. Redding (1972, pp. 436–446) succinctly summarizes the results of these researchers and suggests the following general conclusions:

> 1. The better supervisors tend to be more "communication-minded"; e.g., they enjoy talking and speaking up in meetings; they are able to explain instructions and policies; they enjoy conversing with subordinates. (See especially Funk, 1956; Pyron, 1964.)
>
> 2. The better supervisors tend to be willing, empathic listeners; they respond understandingly to so-called "silly" questions from employees; they are approachable; they will listen to suggestions and complaints, with an attitude of fair consideration and willingness to take appropriate action. (See especially Funk, 1956; Simons, 1962; Kelly, 1963; Zima, 1969.)
>
> 3. The better supervisors tend (with some notable exceptions) to "ask" or "persuade," in preference to "telling" or "demanding." (See especially Simons, 1962; Pyron, 1964.)
>
> 4. The better supervisors tend to be sensitive to the feelings and ego-defense needs of their subordinates; e.g., they are careful to reprimand in private rather than in public. (See, e.g., Simons, 1962.)
>
> 5. The better supervisors tend to be more open in their passing along of information; they are in favor of giving advance notice of impending changes, and of explaining the "reasons why" behind policies and regulations. (See especially Funk, 1956; Simons, 1962.) (Redding, 1972, p. 443)

Other research on superior–subordinate communication contemporary to that of the Purdue group generally supports the thrust of the above conclusions (Brown, 1964; Jain, 1971; Ponder, 1959; Sadler, 1970; Tacey, 1959, Walker, Turner, & Guest, 1956).

For example, Ponder (1959) reports that effective as compared to ineffective foremen tend to be better communicators: They spend more time with employees carrying out the job, providing general supervision, and handling personnel matters. Moreover, more recent research provides additional testimony to the validity of the claims of these investigators (Duffy, 1975; Heizer, 1972; Sank, 1974; White, 1972) or has attempted to further elucidate the communication behaviors associated with various managerial interaction styles (e.g., Bradley & Baird, 1977).

Despite the strong evidence that characterizes the communication profile of effective superiors, other research suggests that effective supervisory communication behaviors are situational and contingent on a variety of factors (e.g., Downs & Pickett, 1977). As Redding (1972) notes in his own review of the Purdue studies, "The precise combination of behaviors or attitudes which 'works' in one company is likely to be different from what 'works' in another company or organization" (p. 445). The importance of viewing effective as compared to ineffective superior communication behavior from a contingency perspective is demonstrated by developments in three areas of leadership research: (a) the traditional study of leadership that employs the "consideration-initiating structure" framework (e.g., Fleishman & Harris, 1962), (b) Fiedler's contingency approach to leadership (e.g., Fiedler, 1967), and (c) a more recent view of leadership that uses a dyadic linkage – role-making model (e.g., Dansereau, Graen, & Haga, 1975).

As a result of extensive leadership research conducted at Ohio State University during the 1950s and early 1960s, two basic dimensions of leadership behavior were identified: (a) "consideration" and (b) "initiating structure." (See Stogdill, 1974, pp. 128–141, for a complete review of these studies.) Leader consideration was found to be typified by friendship and warmth, mutual trust, rapport and tolerance, and two-way communication between a leader and his/her work group (Fleishman, Harris, & Burtt, 1955). Initiating structure includes "behaviors in which the supervisor organizes and redefines group activities and his relation to the group . . . . This dimension seems to emphasize overt attempts to achieve organizational goals" (Fleishman & Harris, 1962, p. 43). These two basic dimensions of leader behavior are analogous to those denoted as "employee orientation" and "production orientation" in the University of Michigan Institute for Social Research leadership studies (e.g., Katz, Maccoby, & Morse, 1950). The importance of the above investigations to the identification of the effective communication behaviors of supervisors rests on the similarity between the constructs of consideration and employee

orientation, and communication. For example, Miraglia (1964), who studied the parallels between consideration and communication ability, discovered that consideration "is largely a matter of *communication* behavior" (Redding, 1972, p. 148). This conclusion has been supported in research by Jain (1973) and more recently in a study by Dennis (1974).

The general conclusion drawn from the early consideration and initiating structure research was that superiors are "rated as more effective when they score high in both consideration and leadership structure" (Stogdill, 1974, p. 140). Perhaps of even greater significance for communication researchers is the general finding that leaders high in consideration (good communicators) can increase structure within their work groups and still be rated as effective leaders (e.g., Fleishman & Harris, 1962). However, current inquiries suggest that numerous situational variables impinge on the validity and reliability of consideration-initiating structure (C-IS) to predict leader effectiveness. Reviewing this literature through 1973, Kerr, Schriesheim, Murphy, and Stogdill (1974) identify the following as situational variables that moderate the C-IS ability to predict leader behavior and performance:

> subordinate need for information, job level, subordinate expectations of leader behavior, perceived organizational independence, leader's similarity of attitudes and behavior to managerial style of management, leader upward influence; and characteristics of the task, including pressure and provision of intrinsic satisfaction. (p. 62)

More recent investigations also suggest that the following situational variables may moderate the C-IS predictive capability: sex (Day & Stogdill, 1972), task type (Hill & Hughs, 1974), length of employment and organizational climate (Kavanagh, 1975), and work-unit size (Schriesheim & Murphy, 1976).

Fiedler's work on leadership likewise indicates that researchers should be examining the communication attributes of effective superiors from a contingency perspective (e.g., Fiedler, 1964, 1967, 1970, 1971a, 1971b, 1972a, 1972b). Emphasizing the role of leader personality and style of interaction on work-group performance, Fiedler argues that three dimensions of task *situations* primarily determine leader effectiveness: leader–member relations (which obviously are dominated by communication behavior), task structure and leader-position power. In essence, this research suggests that supervisors have predominant styles of interacting with subordinates and that their effectiveness will vary, depending on whether the situation (as previously defined) is best suited to that style.

Finally, recent research that views leadership from a dyadic linkage – role-making perspective shows that supervisors do not develop the same kinds of relationships with all subordinates and superiors, and thus the communicative behavior that may be effective in one type of relationship may not be effective in another (Cashman, Dansereau, Graen, & Haga, 1976; Dansereau, Cashman, & Graen, 1973; Dansereau et al., 1975; Graen, Cashman, Ginsburgh, & Schiemann, 1977; Haga, Graen, & Dansereau, 1974). Specifically, results of this research indicate that supervisors tend to develop one of two types of exchange patterns with subordinates, that is, either a pattern of leadership exchange (characterized by "influence over a member without resort to authority" [Cashman, 1976, p. 281]) or supervision exchange (in which "influence over a member is based primarily upon authority" [Cashman et al., 1976, p. 281]). Moreover, it has been found that supervisors in turn develop either leadership exchanges or supervision exchanges with their bosses. In addition, findings suggest that

> subordinate members of the upper dyad who develop leadership exchanges with their bosses have greater influence with their bosses and receive more latitude, support and attention from their bosses than their colleagues who fail to develop leadership exchanges. (Graen et al., 1977, p. 502)

In summary, investigations that explored a dyadic linkage – role-making model of leadership suggest that superior–subordinate communication patterns are not stable across all superior–subordinate interactions and may vary as a function of organizational understructure.

As noted in the opening of this section, we are rich in research studies that have attempted to identify the effective and ineffec-

tive communication correlates of supervision. Clear evidence has been presented that suggests a certain profile that characterizes the communication behaviors of effective supervisors. On the other hand, several other research traditions were reviewed which indicate that the qualities of effective leadership vary from situation to situation and are contingent on numerous factors. Which set of findings and conclusions are we to believe? The answer would appear to be both. Data that comprise the Purdue and other related effectiveness studies have been collected from a myriad of organizations and supervision situations—the pattern of results is too consistent to reject without further research. It may be that for 60% of the superior–subordinate communication situations, these findings are applicable, yet they may only apply to 10% of the cases. Obviously, the only way we will be able to resolve this question is by research that investigates the effects situational variables have on superior–subordinate communication.

Personal Characteristics

In the process of studying superior–subordinate communication, researchers have attempted to discover the personal characteristics of members of that dyad that mediate their communication behavior. Since the variables examined in these investigations are extremely diverse and at present lack coherent organization, this section endeavors to provide such structure.

Several investigators have explored the effects interactant tendencies for internal as compared to external locus of control have on superior–subordinate interaction (Durand & Nord, 1976; Mitchell, Smyser, & Weed, 1975). Findings from these studies suggest (a) that internal subordinates see their supervisors as more considerate than do externals; (b) that internals are most satisfied with participative superiors, whereas externals are most satisfied with directive superiors; and (c) that internal superiors tend to use persuasion to obtain subordinate cooperation, whereas externals rely more on coercive power. In addition, research related to the study of locus of control indicates that subordinates and superiors with passive personalities tend to exaggerate the volume of their interaction with others, whereas active persons tend to underestimate their interaction (Webber, 1970).

Studies that examined the characteristics of supervisors and their communication-related behavior with subordinates suggest the following interesting conclusions: (a) High-least-preferred-co-worker (LPC) leaders under conditions of threat tend to engage in considerate behavior, whereas low-LPC leaders tend to increase initiating structure (Green, Nebeker, & Boni, 1976); (b) lower level supervisors tend to be more dogmatic than upper-middle and top-level managers (Close, 1975); (c) young managers (20–29 years) tend to be more autocratic and low in human relations skills than are middle-aged (30–40 years) or late middle-aged (40–55 years) managers (Pinder & Pinto, 1974); and (d) superiors tend to rate subordinates as competent when they have values similar to those of the superior (Senger, 1971).

On the other hand, studies exploring subordinates' perceptions of superior's communication behavior and personality indicate (a) that superiors who are apprehensive communicators are not particularly liked by subordinates (Daly, McCroskey, & Falcione, Note 3); (b) that subordinate's satisfaction with superiors can be predicted from several dimensions of homophily–heterophily (Daly, McCroskey, & Falcione, Note 4); (c) that authoritarian subordinates are most satisfied when they work for directive superiors (Bass, Valenzi, Farrow, & Solomon, 1975; Tosi, 1973); (d) that subordinate satisfaction with immediate supervision is related to subordinate perception of superior's credibility (Falcione, 1974); (e) that confirmation of subordinate's needs for affection and dominance results in greater perceived frequency of interaction between superior and subordinate (Hawkins, 1976); (f) that subordinates in small work groups, who require high interaction with co-workers and superiors and high interdependence, have negative attitudes toward authoritarian supervisors, whereas subordinates in large work groups, with restricted interaction and highly independent work, have more positive attitudes toward

authoritarian supervision (Vroom & Mann, 1960); and (g) that subordinates, regardless of their personality, tend to be most satisfied with superiors high in human relations orientation (Weed, Mitchell, & Moffitt, 1976). In addition, it should be noted that Hall (1974, 1975) has conducted a series of investigations that examine, in part, personality correlates of organizational members that affect superior–subordinate communication, the results of which are too voluminous to report here.

An area of superior–subordinate research that has received considerable attention of late is concerned with differences between male and female supervisory behaviors. The general results of these inquiries indicate that subordinates do not describe the behaviors of male and female leaders differently (e.g., Bartol & Wortman, 1975; Day & Stogdill, 1972) but do agree on the existence of leader sex role stereotypes (e.g., Rosen & Jerdee, 1973; Schein, 1973, 1975). Specifically, there is strong evidence which suggests that subordinates of both sexes are more satisfied with consideration behavior from a female superior than a male and are more satisfied with exhibition of initiating structure by male superiors than with similar behaviors from female superiors (Bartol & Butterfield, 1976; Petty & Lee, 1975; Petty & Miles, 1976). Moreover, Sussman, Pickett, Berzinski, and Pearce (in press) report that the sexual composition of superior–subordinate dyads does impose "norms and restrictions" on upward communication in the dyad.

In summary, studies that examined the effects of personal characteristics on superior–subordinate communication have tended to focus on three basic areas: (a) single characteristics of superiors or subordinates that affect their communication behavior, (b) characteristics of superiors and subordinates, taken together, and their effect on superior–subordinate communication, and (c) differences in superior–subordinate communication as a function of the sex of the interactants. Although the findings of most of this research are interesting and important, on the whole they tend to be isolated and to lack theoretical foundations. Future investigations should endeavor to remedy this situation by relating such studies to the larger scope of organizational communication theory.

Feedback

Probably one of the most common complaints aired by superiors and subordinates about their communication relationship is that one of the interactants does not provide the other with sufficient and relevant feedback. Both upward and downward feedback appear to be essential for effective superior–subordinate relations, since such feedback provides information that denotes the success or failure of policies and objectives, that suggests the need for corrective actions and controlling mechanisms, and that provides the members of the dyad with knowledge of the other party's sentiments about formal and informal organizational activities. In his collection of theory and research in organizational communication, Redding (1972) provides an extensive review of empirical inquiries that explore feedback in superior–subordinate communication through about 1970 (see especially pp. 39–62). Now classic studies such as Leavitt and Mueller (1951), Smith and Kight (1959), Gibb (1961), Zajonc (1962), Bowman (1963), Haney (1964), Meyer, Kay, and French (1965), Cook (1968), and Minter (1969) are summarized in Redding's anthology. Hence, the following review examines only empirical research conducted in the area of feedback in superior–subordinate communication after 1970.

Studies that examined feedback in superior–subordinate communication since 1970 can be grouped into one of two categories: (a) investigations that explored the effects of subordinate's feedback to superiors on superior's behavior and (b) research analyzing the effects of superior's feedback to subordinates on subordinate's behavior. Investigations in the former category report a number of interesting findings. Brenner and Sigband (1973), who surveyed over 700 managers in a major aerospace firm have found that subordinate's feedback to superiors is greater when

(a) subordinates were told what was to be done with completed assignments, (b) the superior

formerly held the subordinate's position, (c) the superior made the largest proportion of assignments to the subordinate, and (d) the subordinate felt that he could secure clarification of assignments from his immediate superior. (p. 325)

Attempting to determine if a leader's verbal behavior could be altered by manipulating feedback to him/her, Butler and Jaffee (1974) report that positive feedback to a leader made him/her more task oriented, whereas negative feedback increased negative social-emotional behavior (as classified by Bales's Interaction Process Analysis category system). These researchers argue that their results

> indicate that in a production-oriented organization, positive feedback is to be preferred to negative feedback, and negative feedback might have very little to offer if no specific suggestions for changing one's behavior are given. (p. 335)

In a related study, Fodor (1974) explored the effects of a subordinate's disparagement of a superior's competence on the superior's distributions of rewards to subordinates. Results indicated that the superior tended to favor a compliant subordinate who was not an ingratiator. Finally, several studies have also attempted to determine whether the subordinate's feedback to superiors elicits changes in the superior's behavior and, concomitantly, changes in the subordinate's attitudes toward the superior. For example, Hegarty (1974), who used survey feedback methods, found that supervisory performance improved subsequent to subordinate feedback, whereas Burnaska (1976) relates findings which suggest that feedback and subsequent training can quickly change a supervisor's behavior but that worker perceptions of the superior change only with time.

A number of investigations have examined the effects of a superior's feedback to subordinates on the behavior of those subordinates. Harvey and Boettger (1971), in an experiment designed to improve communication in a managerial work group, reported a norm among subordinates against asking superiors for clarification of memos that are unclear or contain double messages. In a preliminary investigation that explored sources of feedback, Greller and Herold (1975) suggest that intrinsic (i.e., psychologically close to the individual) sources of information are seen by workers as providing more feedback than sources that are seen as external (i.e., psychologically distant). Moreover, in a related study, Kim and Hamner (1976) provide evidence that evaluative supervisory feedback to subordinate performance (i.e., extrinsic feedback) and nonevaluative feedback (i.e., subordinate self-generated or intrinsic feedback), when combined with a goal-setting production program, increase subordinate performance significantly beyond that of groups involved in just goal setting. Recent research also suggests (a) that superiors' feedback to a subordinate, which shows a lack of trust in the subordinate, results in subordinate dissatisfaction and aggressive feelings (Brenenstuhl, 1976); (b) that superiors perceived as expressive (high in human relations) are more likely to provide subordinates with social approval than those superiors perceived as instrumental (a Weberian orientation) (Marcus & House, 1973); (c) that in conflict situations supervisory responses that relate acceptance and encouragement of subordinate disagreement are associated with high subordinate satisfaction (Burke, 1970; Renwick, 1975); and (d) that under low surveillance (infrequent need to report to superior) positive feedback from superior to subordinate leads to greater subordinate compliance than when the subordinate receives no direct feedback, whereas under high surveillance conditions subordinates who receive positive feedback from their superiors comply less than when they receive no direct feedback from their superiors (Organ, 1974).

In addition, a variety of research has explored the effects of superior reward or reinforcement behavior on subordinate performance and satisfaction. These studies suggest the following conclusions: (a) Leader positive reward behaviors (e.g., recognition of subordinate performance) are generally associated with subordinate satisfaction, but the relationship between leader punitive rewards (e.g., corrective actions) and subordinate satisfaction varies as a function of the nature of the task performed by each work group (Sims & Szilagyi, 1975); (b) superiors who frequently criticize their subordinates for

poor work are generally rated as less effective than those who criticize less frequently (Oldham, 1976); and (c) a superior tends to positively reinforce a subordinate when he/she is positively reinforced by the subordinate's performance and to negatively reinforce a subordinate when he/she is negatively reinforced as a result of the subordinate's performance (Barrow, 1976; Greene, 1975; Hinton & Barrow, 1975; Lowin & Craig, 1968).

It should also be noted that research discussed earlier by Stull (1975) and Jablin (1978a) indicates that both superiors and subordinates prefer message responses from one another that provide positive relational feedback to the source of the message. In addition, Hill's (1973) findings suggest a significant tendency for subordinates to perceive their bosses as using one style of response to "handle interpersonal problems and another, different style to tackle technical problems" (p. 45).

In summary, results of investigations since 1970 that inquired into the nature of superior–subordinate feedback processes are generally consistent with conclusions from earlier research. Feedback from superiors to subordinates appears to be related to subordinate performance and satisfaction. However, at the same time, findings suggest that the subordinate's performance to a large extent controls the nature of his/her superior's feedback. Thus, present evidence indicates that future research should continue to explore the reciprocal character of feedback in superior–subordinate relationships, with particular emphasis on specific influence mechanisms.

Systemic Variables

Researchers have long been concerned with the effects that systemic organizational variables (e.g., technology, control structure, hierarchy, environment) have on the quality and nature of superior–subordinate communication. However, without doubt, less empirical as compared to theoretical research has been conducted in this area.

The exact role of technology in determining communication in organizations has puzzled researchers for at least two decades. For example, in the late 1950s Simpson (1959) found what he believed was the critical variable mediating the flow of vertical and horizontal communication in organizations: the degree of "mechanization" of work processes. Trist and Bamforth (1951), Gouldner (1954), Woodward (1958, 1965, 1970), Lawrence and Lorsch (1967), Perrow (1967), Pugh, Hickson, Hinings, and Turner (1969), and Peterson (1975), among others, all report findings which suggest that organizational members' perceptions of organizational and communication climate are linked to technological processes within organizations. Of even greater significance is Dubin's (1965) discovery that what is considered effective supervision may, in part, be a function of an organization's or work group's technology. Moreover, a recent doctoral study by Derry (1973) directly examined the effects technology and hierarchical position have on supervisory style, "communication responsiveness," and social interaction strategy. Results from two technologically diverse units within a manufacturing company (i.e., a manufacturing group and a research and development unit) indicated different patterns of superior–subordinate communication, depending on the interaction between technology and hierarchy.

Several investigations have also examined the relationship between organizational strucure and participant communication behavior (e.g., Bass, 1976; Blankenship & Miles, 1968; Ghiselli & Siegel, 1972; Porter & Lawler, 1964). Findings from these studies suggest the following conclusions that are relevant to superior–subordinate communication: (a) Upper level managers tend to involve their subordinates more in decision making than do lower level managers, whereas lower level managers tend to have decisions initiated for them by their superiors (Blankenship & Miles, 1968; Jago & Vroom, 1977); (b) "as compared with firms which have tall organizational structures, those which have flat structures reward with more rapid advancement those managers who favor sharing information and objectives with subordinates" (Ghiselli & Siegel, 1972, p. 622); and (c) in situations that are "regular, clear and structured," authoritative managerial direction is frequent, but subordinates often perceive such

direction "to be more effective under reverse conditions" (Bass, 1976, p. 215).

In summary, empirical research that has examined the relationship between systemic organizational variables and communication between superiors and subordinates has tended to focus on one of two areas: (a) technology or (b) organizational structure. However, the major portion of this research has often been simplistic and/or of limited generalizability. Future research in this area is sorely needed, for if we are to ever understand the micro system of superior–subordinate communication, we must first explicate its relationship with variables in the organization's macrosystem.

Discussion

This literature review has attempted to organize into nine topical categories empirical research on superior–subordinate communication. A close examination of this research suggests a number of conclusions. First, inspection of the variables explored within each category indicates that several basic constructs appear in more than one grouping. Specifically, we find at least three items that are consistently being studied: (a) the effects of power and status on superior–subordinate communication, (b) trust as a moderator of superior–subordinate communication, and (c) semantic-information distance as a source of misunderstanding in superior–subordinate communication. Moreover, these three variables tend to be explored concurrent to one another rather than in isolation of each other. Power and status differentials are an inevitable result of organizational development and in part serve as the impetus for the semantic-information distance between superiors and subordinates. However, the relationship of interpersonal trust to these variables is not perfectly clear, since in some situations it facilitates openness and understanding between superior and subordinates, whereas in other circumstances it appears to have no effect whatsoever. Moreover, there is some empirical and theoretical evidence (e.g., Sussman, 1975) which suggests that superior–subordinate semantic-information distance is a valuable and important feature of organization and that too large an attenuation of this gap may have dysfunctional consequences for organizational effectiveness. In short, the relationship between superior–subordinate semantic-information distance and organizational effectiveness may be a curvilinear association and may be one that is differentially moderated in various situations by interpersonal trust and perceived power and status differentials between the interactants. Obviously, additional multivariate research is required before we can fully understand the relationships between interpersonal trust, power and status, semantic-information distance, and superior–subordinate communication.

The second major conclusion to be drawn from the preceding review of literature is that a contingency/situational approach to the study of superior–subordinate communication is necessary. Repeatedly, we find that situational variables moderate the type and quality of communication exchanged between superiors and subordinates. Furthermore, if future research confirms the above proposition, much of the existing literature relating to superior–subordinate communication will become suspect and will require replication and clarification within and between organizations. In addition, it is essential that researchers start to explore the effects systemic organizational variables have on superior–subordinate communication, for as Graham and Roberts (1972) observe,

> we will only increase our understanding of organizational behavior as more researchers simultaneously investigate individual, group and organizational variables within organizations, and between organizations and the effects of environmental factors on those components. (p. 130)

Moreover, it is likely that such an approach will be more conducive to theory building in the area of superior–subordinate communication and organizational communication in general.

Finally, this review and interpretation of the literature identifies a need for some changes in the research questions we are asking about superior–subordinate communication and in the methods that are employed to answer those questions. At present, the majority of investigations exploring superior–subordinate communication have focused on

describing the various problematic states of superior–subordinate relations. For example, we can describe with a fair degree of confidence an open and closed superior–subordinate relationship, the communication qualities and characteristics of effective supervisors (for at least a limited number of situations), and the types of messages that tend to be distorted in upward communication. However, a much smaller amount of research has been directed towards discovering the antecedents to these conditions. For instance, we need to start asking questions such as How do open and closed superior-subordinate communication relationships develop? How do initial attributions and expectations of new superior–subordinate relations affect subsequent communication behavior? What stages of growth are characteristic of superior–subordinate communication relationships? How do superior–subordinate communication patterns change over time, and what causes these changes? And, of course, while these questions are being explored, a contingency orientation within our research investigations should be maintained. As Redding (1972) has observed, "the *contingency* nature of most generalizations about organizational phenomena should be kept in mind when interpreting the findings of studies dealing with supervisory communication" (p. 439).

The approach that Graen and his associates have employed to study dyadic linkages in superior–subordinate leadership exchanges provides an excellent model for the general study of superior–subordinate communication. Specifically, these researchers have attempted to trace the development of superior–subordinate relations from their initiation through the emergence of stable interaction patterns. In other words, they have used a developmental and longitudinal research design in exploring leadership behavior. Such an approach also appears to be ideal for the study of superior–subordinate communication, since it can provide descriptive, analytical, and often quasi-experimental data about superior–subordinate relationships. It should also be noted that a growing body of research is emerging that explores the relationships between applicant job expectations and employee attitudes, satisfaction, and so forth subsequent to employment in an organization (e.g., Ilgen & Seely, 1974; Katzell, 1968; Wanous, 1973). Information from these studies that relates to potential characteristics of superior–subordinate communication can serve as the initial point to begin our inquiries into the development of superior–subordinate communication patterns. In summary, combining our current knowledge of superior–subordinate communication with future studies that examine the dyad from a developmental, longitudinal perspective appears to provide the most promise for increased understanding of the phenomena we call superior–subordinate communication.

Clinical Applications of Hypnosis to Three Psychosomatic Disorders

Frank A. De Piano and Herman C. Salzberg
University of South Carolina

Studies of hypnosis in the treatment of skin disorders, headaches, and asthma were reviewed in terms of outcomes and methodological soundness. Some studies focused on changing physiological functions, others on increasing insight in their patients, and still others on altering patients' perceptions of their symptoms. Methodological weaknesses included lack of control groups, nonrandom assignment of patients to treatment conditions, and confounding of treatment effects or lack of control for placebo effects. Additional weaknesses centered around the use of single outcome measures and the failure to assess the specific roles of mediating variables. Most of the studies reviewed showed positive treatment effects. However, there is equivocal evidence that hypnosis can directly influence autonomic functioning. Hypnosis may be valuable in facilitating one's capacity to gain insight into how one's symptoms developed and are maintained. In addition, hypnotic procedures have resulted in some success when used to indirectly alleviate symptoms by altering how individuals perceive their disorders and how these disorders affect their lives.

Hypnosis has become an accepted mode of treatment in both medicine and clinical psychology. Its judicious use was endorsed by the American Medical Association in 1958 and by the British Medical Association in 1955. In 1960, the American Psychological Association sanctioned its use in clinical practice (Hilgard, 1968). Several societies are devoted to the professional study of hypnosis, and both psychology and medical training programs offer courses in it.

This article reviews the published reports of the clinical application of hypnosis to skin disorders, headaches, and asthma. The review covers the period from 1967 to 1977 comprehensively, as well as reports prior to 1967 that had a substantial impact on the field.

Hypnosis is most frequently associated with suggestibility. Barber (1974) and his collaborators have, in essence, equated the two by arguing that subjects, when given direct suggestions without a hypnotic induction, displayed behavior similar to that of subjects given a formal induction. Other investigators have adhered to the conceptualization of hypnosis as an altered state of consciousness (Fromm, 1977; Hilgard, 1968). In either case, its investigation as a treatment adjunct for psychosomatic disorders would be justifiable. However, expectations for success might vary with the definition that the investigator accepts.

Although there is disagreement about which specific ailments are psychosomatic and which are primarily organic, it is widely accepted that psychosomatic disorders are etiologically related to or are exacerbated by psychological factors, even though physical symptoms are present and medical intervention is often necessary. Some practitioners argue that illness is always a psychosomatic event. Others merely label a disorder psychosomatic when physical causes are not readily identifiable. Obviously, an investigator's view of a disorder as psychosomatic would influence the decision to use hypnosis in a particular case, which might, in turn, affect the outcome of treatment.

Requests for reprints should be sent to Herman C. Salzberg, Department of Psychology, University of South Carolina, Columbia, South Carolina 29208.

Most investigators do not present theoretical arguments for using hypnosis with psychosomatic disorders. Therefore, much must be inferred. From the theories that are discussed in the literature, three rationales seem to emerge. First, there are those who contend that through hypnosis and hypnotic suggestions, certain autonomic nervous system functions, which are not readily controlled by the individual, come under voluntary control and mediate symptom changes. For example, Clawson and Swade (1975) contend that blood flow to internal organs and limbs can be controlled.

Next, there are investigators who use hypnosis for its assumed capacity to assist patients in gaining insight into how their symptoms develop and are maintained. Once this insight is achieved, it is further assumed that individuals will be able to solve their problems, thus eliminating the symptoms.

Finally, there are investigators who use hypnosis to alter the way in which one's disorder is perceived. For example, suggestions are given that the symptoms will no longer concern the patient. This altered perception has two potential effects. First, the patient can become less debilitated by these symptoms and thereby can function more effectively, and second, the emotional component of the disorder, which may exacerbate the condition, can be reduced.

Research articles have occasionally appeared that investigate the use of hypnosis in treatment of other psychosomatic disorders, such as Raynaud's disease, arthritis, seizures, stomach disorders, Gilles de la Tourette's syndrome, hypertension, and so forth. Hypnosis research has been reported most frequently in the treatment of skin disorders, headaches, and asthma. Therefore, the present review has been limited to these three disorders.

Methodological Considerations

As is true of much clinical research, studies of hypnosis in the treatment of psychosomatic disorders reflect many methodological shortcomings. Understandably, in a clinical setting, it is frequently extremely difficult to establish proper controls. Considerably more than half of the studies reviewed were single- or multiple-case reports. A few used a treatment group procedure but did not include a comparison group. Of the remaining controlled studies, some did not randomly assign subjects to treatment conditions.

A glaring weakness across the majority of studies was the lack of specification of the hypnotic procedure used. Few studies discussed the induction technique in detail, and even fewer reported the use of a reliable instrument for assessing whether the patient was hypnotized. An additional widespread shortcoming was the lack of control for experimenter bias, which could have been accomplished by keeping the experimenter blind to patient treatment group.

Methodological weaknesses were also noted in terms of the outcome measures employed. Self-report and physicians' impressions were most frequently used. Physiological change was assessed on occasion. A combination of both objective and subjective measures, however, was infrequently reported.

Finally, none of the studies that were reviewed employed an acceptable control for placebo effects.

A summary of the studies can be found in Table 1, which includes an indication of whether the treatment was successful (+) or unsuccessful (−), time interval of follow-up, type of design (case, treatment group, treatment and control condition), whether or not subjects were randomly assigned, and the number of patients/subjects studied.

Skin Disorders

Hypnosis is commonly used as one form of treatment for skin disorders because of the generally assumed association of skin responses and the autonomic nervous system. Both the skin and the autonomic nervous system develop embryologically from the ectoderm, and correlations between self-report of the normal responses to embarrassment with blushing and to fear with blanching and goose pimples are well accepted (Jabush, 1969). The types of disorders treated include psoriasis (a condition characterized by reddish and silvery scales), dermatitis (an inflamation of an area of the skin), boils (pyo-

[a] + indicates that treatment was successful; − indicates that treatment was unsuccessful.

genic infections originating in hair follicles), and warts (thickenings of the Malpighian and granular layers of the epidermis).

Physiological changes. A number of single- and multiple-case studies have reported the successful application of hypnosis to various skin disorders, for example, Twerski and Naar (1974), refractory dermatitis; Jabush (1969), boils; and Tasini and Hackett (1977), Clawson and Swade (1975), Vollmer (1946), and Ewin (1974), warts. These investigations did not take into account baseline rates of spontaneous remission, and in addition, they often confounded the effects of hypnosis with other treatment effects. Although several investigators hypothesized that autonomic changes would occur through hypnosis, no physiological measurements were made.

Surman, Gottlieb, Hackett, and Silverberg (1973) conducted a controlled investigation of the effects of hypnotic treatment of warts. Seventeen patients were told, during each weekly hypnotic session, that they would experience a tingling sensation in the warts on one side of their body and that only those warts would subsequently disappear. Treatment continued for 5 consecutive weeks. Seven patients served as a waiting list control group. The authors concluded that warts respond to hypnosis but that hypnotic suggestion does not affect them selectively. There were, however, critical differences between the treatment and comparison groups. The average duration since the appearance of the warts had been 2.8 and 3.9 years, respectively, for these groups. As reported by the authors, warts spontaneously disappeared, on the average, 2.28 years after onset. It may well be that the warts of the patients in the comparison group were resistant to remission over time, whereas those in the treatment group were less resistant. The conclusion that hypnotic suggestion can eradicate warts becomes even more suspect when, although none of the 7 control subjects lost any warts during the 3-month treatment period, one of them, who was scheduled for postexperiment hypnotherapy, spontaneously lost all but one wart before the first treatment session.

The few well-controlled studies that investigated physiological changes were not performed on clinical populations. In a laboratory study conducted by Peters and Stern (1971), it was hypothesized that blood pressure, skin temperature, and pulse rate would increase in subjects given suggestions of hives and would decrease in those given the suggestion that they would show symptoms (peripheral vasoconstriction) associated with Raynaud's disease. These effects had been observed during the natural occurrence of these disorders. Subjects were well screened for hypnotic susceptibility before entry into the experiment. There were four treatment groups, each of which received two sessions. Group 1 received suggestions for hives while hypnotized in Session 1 and suggestions for symptoms of Raynaud's disease with method acting instructions in Session 2. Group 2 received the same treatment as Group 1, with sessions given in reverse order. Group 3 received suggestions for symptoms of Raynaud's disease while hypnotized, then hives suggestions with method acting instructions. Group 4 was treated identically to Group 3, with sessions administered in reverse order. Although Peters and Stern did not elaborate on what they meant by method acting, it appears to be similar to role playing. Results did not support the contention that specific changes would occur depending on suggestions given during hypnosis. It was observed, however, that hypnotized subjects, regardless of the suggestions given, did show a decrease in skin temperature and blood volume in the fingers.

In a second well-controlled nonclinical experiment, conducted by Johnson and Barber (1976), the effects of hypnotic suggestion on blister formation were examined. This study was especially noteworthy for its attempt to control many of the factors that possibly influenced results of earlier studies, including (a) direct observation of subjects, to eliminate the possibility that skin changes might be a function of self-injurious behavior; (b) procedures to insure that the experimenter remained blind, to reduce the possibility of experimenter bias; (c) an evaluation of hypnotic susceptibility; and (d) an evaluation of skin sensitivity, to assess its influence on skin change. An additional strong point of this study was the assessment of skin temperature

changes, which were assumed to mediate blister formation, in addition to the direct observation of external changes of the skin.

None of the experimental subjects displayed any true blisters. In addition, only 2 of the 48 subjects displayed visible skin changes. In both of these subjects, changes could be attributed to factors other than hypnotic suggestion. No differences in temperature were found between the test hand and control hand. Comparison of susceptible versus nonsusceptible subjects revealed no differential change in hand temperature. The actual data were not presented, however, making it impossible to determine if this nonsignificant finding was due to a lack of a cause–effect relationship or because of a lack of statistical power, due to the small number of subjects who were considered susceptible. Although the study indicated that the general population may not show physical changes in response to suggestion, it does not preclude the possibility that subjects who spontaneously develop blisters (and other skin disorders) might respond positively to suggestion.

Insight. Several case studies illustrate how hypnosis was used to help patients gain insight into the development and maintenance of their symptoms.

Ewin (1974) reported on three cases of successful treatment of conyloma acumatum (warts on the genitalia or perineal region). The first case met with initial failure when suggestions for direct physiological changes were made. After this failure, the assumption was made that the warts were serving some purpose not consciously perceived by the patient. While hypnotized, the patient revealed that he had been engaging in extramarital intercourse, which he thought might be having a deleterious effect on his marriage. The warts were restricting this extramarital activity, thereby bringing the patient closer to his wife. During hypnosis, it was suggested that this type of problem solving was inefficient. Within 3 weeks of this single session, all the warts disappeared. In a second similar case, a male patient revealed, while hypnotized, that his warts kept him from engaging in extramarital relationships. He was told that his behavior could be consciously controlled and that the warts were unnecessary. Two-and-one-half months later, the warts were two thirds gone, with complete remission occurring 1 month later. In a third case, suggestions without hypnosis, were given to a male homosexual with a rosette of perineal warts. It was suggested to the patient that he feared anal rape, and that he should forget about protecting his anus with this ring of warts. One month later, the author reported 50% remission, and after one additional session with hypnosis, complete remission was claimed. In each of these cases, length of time between initial treatment and eventual cure ranged from 2 to 3½ months. Spontaneous remission of symptoms might have occurred during that time.

French (1973) described the successful treatment of a woman who suffered from venereal warts. While hypnotized, the patient recalled that the warts first appeared during a gratifying sexual affair. During this session the patient was told that she had to choose between keeping both the affair and the warts or relinquishing the affair and thereby the warts. The woman chose to give up the affair and the warts. After 3 weeks it was reported that she was greatly improved, with complete recovery noted after 5 weeks.

Frankel and Misch (1973) reported on a case of long-standing psoriasis in which hypnosis was used to help a patient gain insight. After several sessions that used hypnotic suggestion to influence symptoms directly, the patient was requested to discuss his resistance to relinquishing his psoriasis. He stated that he realized that maintenance of the symptom allowed him the comfort of avoiding threatening social interactions. After 8 weeks, the patient had improved considerably. The authors indicated that in addition to the self-report and observations of improvement, there was also a 2.1 °F. (1.17 °C) increase in skin temperature from the beginning of the trance to its completion. It was impossible to determine, however, whether this change was a function of hypnosis, suggestion alone, emotional changes, or a byproduct of a spontaneous remission of the condition.

Altered perception. This final pair of investigations employed hypnosis with skin disorders to alter the subjective perception and/or reduce the discomfort created by the symptoms.

Ament and Milgrom (1967) found hypnotic suggestion to be successful in the treatment of a case of pruritus. After the first session, decreased pruritus was reported with additional improvement noted after each subsequent session. After five sessions, however, a previously suspected diagnosis of myelocytic leukemia was made. For the following 2 months, the patient's skin remained generally in good condition. It cannot be known with certainty, however, what psychological effect the development of leukemia may have had on the patient and consequently on the pruritus condition.

In a second series of cases presented by Klinge (1971), three dermatitis patients were successfully treated with hypnotic suggestions and subsequently perceived their symptoms as less severe. Unfortunately, this treatment effect was confounded by simultaneous treatment with vitamin A, hydrocortisone, and bandaging.

It appears that well-controlled studies of skin disorders have not substantiated the case study findings of physical change associated with the hypnotic treatment. Evidence for autonomic changes, which are often assumed to mediate external skin changes, was typically absent, or the autonomic changes were not measured. Although inconclusive because of the lack of control for spontaneous remission, there were several interesting instances of symptom improvement as a result of the use of hypnosis to help patients gain insight into the maintenance of their symptoms. Some success, although limited to a small number of cases, was also reported as a result of attempts to alter perceptions and reduce the discomfort created by these symptoms.

Headaches

A second disorder that is commonly treated with hypnosis and hypnotic suggestion is headache. Migraine and tension headaches are most commonly treated. Migraine headaches are thought to be initiated by constriction of the blood vessels to the head and brain, which is followed by overcompensation, causing the vessels to become enlarged. This expansion is credited with causing the unilateral pain, dizziness, nausea, and blurred vision associated with migraine (Wolff, 1963). Traditional treatment consists of two interventions, one aimed at inhibiting the initial constriction of the vessels, the other aimed at reducing the dilation of blood vessels after onset of the headache (Graham, 1975). Tension headaches, on the other hand, are a result of prolonged muscular contractions (usually associated with stress) about the face, scalp, and neck. Behavioral treatment generally consists of deep muscle relaxation training or biofeedback.

Physiological changes. Successful treatment of individual cases of migraine headache has been reported by Ansel (1977) and Graham (1975) and of tension headaches by Todd and Kelly (1970). Treatment of 25 cases of intractable migraine was reported by Harding (1961). All of the patients' symptoms had become progressively worse despite previous drug treatments. Hypnosis was recommended as a last resort. Treatment consisted of four sessions that included history taking, explanation of migraine, and hypnotic suggestions that the patients picture the blood vessels in their heads growing smaller and returning to normal. Improvement was assessed in two ways: through self-report and through the hypnotist's impressions. Five had complete remission, 10 showed substantial improvement, and 5 experienced some relief. Five patients showed no improvement at all. Three of the 5 failures were reported not to be hypnotizable. This study is noteworthy for the effort made to systematically treat a number of patients with a standard approach. However, no report of the successful patients' hypnotizability was made, thus preventing an assessment of the relationship between hypnotizability and treatment success.

Cedercreutz, Lahteenmaki, and Tulikoura (1976) treated 155 consecutive skull-injured patients who had been experiencing headache and vertigo for 1 week or longer after their injury. Treatment consisted of between 1 and 10 weekly sessions. During hypnosis, therapeutic suggestions were repeated several times.

Trance capability was assessed by the investigators on a 4-point rating scale. The authors reported that although 58% of the 120 headache patients who were rated as achieving a light trance or above were symptom free 22 months later, none of the nonhypnotizable patients were improved. It was further pointed out that a strong relationship between the duration of the symptoms and the likelihood of therapeutic benefit existed. The likelihood of obtaining relief was markedly greater if therapy began shortly after the original trauma. The conclusion of Cedercreutz and his collaborators, that hypnosis is an appropriate treatment procedure for those patients with posttraumatic skull injuries who complain of headache and vertigo, does not necessarily follow, however. Earlier investigators, including Cedercreutz and Kampman (1972), found that in 3- to 4-year follow-ups on skull-injured untreated patients, 30%–34% still suffered from headaches (conversely 66%–70% spontaneously recovered). The present study, although it reported that 50% of the headache patients completely recovered and 20% partially recovered, did not take into account the base rate of spontaneous remission. Similarly, their finding that successful treatment was negatively correlated with the length of time between injury and the onset of treatment may be misleading. The symptoms of those patients who were treated long after their injury were evidently persistent and not likely to disappear over time, whereas patients who were seen immediately after an accident would be more likely candidates for spontaneous remission.

In a controlled study conducted by Andreychuk and Skriver (1975), biofeedback was compared to hypnosis as a treatment for migraine. In addition, the role of suggestibility in treatment was examined. Thirty-three established migraine sufferers were randomly placed in one of three groups: hypnosis treatment, hand warming training, or alpha enhancement training. All groups showed significant improvement from the baseline to the completion of 5 weeks of treatment. No treatment was found to be superior. Highly susceptible patients responded better than less susceptible ones, regardless of the type of treatment received. The initial goals of the biofeedback and hypnotic treatments differed, however. Biofeedback had as its intermediate goal the increase of blood flow and temperature in the hand, whereas the hypnosis treatment was geared exclusively to influence the headaches. It would have been valuable to set as an intermediate goal for both groups an increase in hand temperature and blood volume and to assess these goals prior to evaluating the effectiveness of each treatment in terms of symptom removal.

Anderson, Basker, and Dalton (1975) compared the effects of hypnotherapy and autohypnosis with a drug treatment program of Stemetil. The authors reported a difference in both number and intensity of attacks between the 6-month baseline and the first 6 months of hypnotic treatment. Stemetil treatment did not result in significant change. There was, however, no control for the added personal contact between physician and patient in the hypnosis treatment group, which could have accounted for the greater improvement obtained.

Insight. Blumenthal (1963) reported the successful treatment of two headache patients. The first patient had suffered with persistent pain over the left side of her neck and occiput. Through hypnosis, the patient recalled that her stepfather, who on several occasions had attempted to seduce her, had commonly placed his hand on her face and neck to comfort her and show her affection. In the second case, a Catholic father of five suffered from migraine headaches and complete sexual impotence. While hypnotized, he revealed that he was concerned about making his wife pregnant. Blumenthal hypothesized that the headaches served as a subconscious "displacement for his sexual feelings of erection and engorgement into the full engorged throbbing vascular headache" (p. 201). An exact report of the therapeutic procedures was not presented.

Altered perceptions. Kroger (1963) told headache patients, while they were hypnotized, to imagine their hand in ice water. They were then told that their hand was numb and anesthetized and that they could eliminate the pain in their head by placing this hand next to their head and face. Posthypnotic

suggestions that future headaches could be reduced in the same fashion were given. Kroger claimed that this procedure was successful but presented no data to corroborate the claim.

The case studies on headache fail to meet many of the previously mentioned methodological requirements. The treatment groups and controlled studies, in spite of the methodological problems mentioned, seemed to indicate that hypnosis may be a useful treatment adjunct for headaches. Again, as was found in the treatment of skin disorders, there were several interesting reports of using insight and altered perceptions to alleviate symptoms, but these too were methodologically unsophisticated.

Asthma

The third major psychosomatic disorder that was treated with hypnosis is asthma. Although there is no consensus as to the precise etiological factors involved in asthma, most authors agree that there is some interaction among psychological, infective, and allergic factors. Emotional factors are thought to be aggravating or triggering influences that induce the asthma attack in some patients (Peshkin, 1967). It is believed that anxiety that is associated with an anticipation of the symptoms themselves often results in an exacerbation of the symptoms (Hanley, 1974). Symptoms remain consistent even though causes may vary. During an attack, the air passages, including the trachea, major bronchi, and peripheral bronchioles, constrict. Bronchiospasms and increased secretion of mucus are also present. These physiological changes are responsible for the wheezing and difficulties in breathing seen in most asthmatic attacks.

Physiological changes. In an investigation by Dennis (1965), five good hypnotic subjects who had chronic asthmatic symptoms were exposed repeatedly to a true allergen and a placebo. Each exposure was given with suggestions for allergic reactions and no allergic reactions. This was done while the subject was either hypnotized or in the waking state. Patients were given a suggestion to experience a feeling of coolness. This presumably would induce vasoconstriction and thereby reduce asthmatic symptoms. Reactions to placebo could not be evoked in either the hypnotic or nonhypnotic conditions. However, allergic reaction to true allergen was successfully inhibited in the hypnotic condition. No attempt at monitoring the physiological mechanisms (i.e., vasoconstriction), which were assumed to mediate change in symptoms, was reported.

Weiss, Martin, and Riley (1970) found that suggestions of an asthma attack alone failed to produce allergic reactions in all but 1 of 16 asthmatic children, when they were presented with a saline solution. The 1 subject who reacted was thought to be allergic to the saline solution that was used in the bronchial challenge test.

Smith and Burns (1960) treated 25 chronic asthmatic children, ages 8–15. Hypnosis was achieved in all patients, and suggestions were given for symptomatic relief from asthma. Only objective measures of respiration were obtained, such as vital capacity and forced expiratory capacity. After four weekly sessions, no improvement was noted. These negative findings may be attributed to the unusually brief treatment and the sole use of physiological assessment.

Mun (1969) provided 10 asthmatic children with a series of treatments including one based on hypnotic suggestion. Each child was trained in hypnosis and was easily capable of entering into a trance. Each child, on the onset of an attack, was requested to report to the investigator for treatment. After the child reported, peak flow rate (a laboratory technique for assessing lung functioning) was measured, followed by one of four treatments. After 15 minutes of treatment, peak flow as well as self-report measures were obtained. Treatments consisted of Tedral medication after the first attack, Isoprenalinenebulizer during the second, hypnosis and hypnotic suggestions for symptom removal during the third attack, and Tedral medication and hypnotic suggestions during the fourth attack. Improvement was reported across all treatments, with hypnotic suggestion treatment showing the greatest effects, followed by the combined treatment of Tedral and hypnotic suggestion. No statistical analysis for any of the treatment comparisons was reported and treatment effects were obviously confounded.

Aronoff, Aronoff, and Peck (1975) reported on 17 asthmatic children who chose hypnotic treatment over traditional medical treatment. Hypnotic suggestions for symptom reduction were given during an actual asthmatic attack. Improvement was assessed in terms of physiological change and self-report. However, positive expectations for treatment and an expected decline in symptoms following the peak of an attack confounded the effects of hypnotic suggestion.

Philipp, Wilde, and Day (1972) looked at the effects of nonhypnotic suggestion on two types of asthma patients, those who reacted to skin testing (allergic) and those who did not (emotional). Both groups were subjected to two treatments, suggestions of a reaction when exposed to a neutral drug and suggestions of no reaction when an active drug was presented. Outcome measures included assessment of vital capacity and forced expiratory volume. It was found that emotionals reacted more to suggestions for symptoms on exposure to a neutral drug than did allergics. Another reported finding was that relaxation training across both groups tended to improve respiratory efficiency.

In a well-controlled study conducted by Fry, Mason, and Pearson (1964), the effects of hypnotic suggestion on allergic reactions to known allergens was assessed. Forty-seven asthmatic patients, who had displayed positive skin reactions to extracts of pollen or house dust and who were hypnotically susceptible, served as subjects. In the first part of the investigation, 18 subjects were randomly placed in either a control group, in which two skin tests were conducted, or in an hypnosis group, in which hypnotic suggestions for no skin reactions were given. Each subject was administered four solutions of varying strengths of an allergen. Results indicated that controls showed mixed reaction in terms of size of wheals after an exposure to allergens, whereas hypnosis subjects consistently showed a decrease in wheal size. In the second part of the investigation, 29 subjects were randomly divided among three groups: One received hypnotic suggestions that the right arm would not react to skin tests, another received suggestions that neither arm would react to testing, and the third received hypnosis with no suggestions. All groups showed marked decreases in wheal size. No differences were noted between the treatment groups, with hypnosis alone yielding as great a change as when it had been combined with suggestions.

Insight. Surprisingly, none of the asthma studies that were reviewed used hypnosis as a means of assisting patients in gaining insight into the maintenance of their symptoms.

Altered perceptions. The goal of the following investigations was to change the patients' perception of their symptoms so as to reduce the stress related to them and thereby reduce the intensity of the symptoms themselves.

Hanley (1974) described two cases in which hypnotherapy was used as a treatment for asthma. Therapy consisted of hypnotic suggestions to increase the individual's self-confidence, especially in controlling the asthmatic symptoms. Both patients reported some improvement in symptoms and in day-to-day living. It is not known, however, what effect the physician's supportive statements may have had without hypnosis.

Smith (1970) found, in two female subjects, an increase in pulmonary resistance following direct hypnotic suggestions of coughing, fear, anger, or of an imminent asthmatic attack and a decrease in resistance following suggestion of relaxation. Recall of previous asthma attacks could have been sufficient to create the change in pulmonary resistance.

Edwards (1960) used hypnotic suggestions for symptom reduction and a decrease in the psychological effects caused by an attack in six chronic asthma patients. Three assessment measures were employed: the patient's own testimony, stethoscope monitoring (physician's impression), and ventilatory function tests (vital capacity and forced expiratory volume). During and after treatment, patient reports revealed that their conditions improved. Physiological changes were not found, however. Although the author discussed the difficulty in making claims about treatment from a small uncontrolled study such as the one that he presented, this was not the most serious methodological flaw. Each of the cases were treated at the peak of an acute asthmatic attack. A regression

toward the mean would be expected on the assessment following the crisis, thus casting doubt on any claims of self-rated improvement due to treatment.

In a second investigation by Mun (1969), children were hypnotically age regressed to the time of their first attack and were told that the cause of the first attack was no longer operative and that they should no longer have fear and tension about the constantly recurring need to breathe. Mun reported improvement in self-ratings and objective measures, but, again, he presented no data to support these claims.

Moorefield (1971) described the successful treatment of nine patients with chronic asthma. Hypnotic procedures included suggestions for reduced tension and anxiety, for the ability to breathe easier, and for increased confidence during stress. Patients were seen for an average of 13.4 1-hour sessions. Complete recovery in all but one patient was reported. The effects of the hypnotic suggestions were confounded, however, since the patients were simultaneously treated with systematic desensitization.

The data on 121 asthmatic patients who were treated with hypnotherapy were analyzed retrospectively by Collison (1975). Treatment consisted of hypnotic suggestions that were intended to improve the patients' ability to cope with their environment and to assist them in obtaining both physical and mental relaxation. Posthypnotic suggestions for continued relaxation as well as training in autohypnosis were provided at each session. Patients were also classified according to the depth of trance typically achieved. Results indicated that 21% of the patients remained completely free of asthma attacks through the follow-up. Thirty-three percent showed improvement but continued to have mild attacks. Twenty-two percent improved, but symptoms were still moderately severe. Finally, 24% showed no changes from pre- to posttreatment. Patients who were rated as good hypnotic subjects received the most therapeutic benefit, whereas none of the patients who were poor hypnotic subjects became symptom free. Collison acknowledged that a retrospective analysis only allows for limited inferences. In addition, all patients had volunteered for hypnotherapy, which suggests that they may have had preexisting positive expectations for hypnosis. The care that Collison took in compiling his data was, nevertheless, commendable.

White (1961) hypnotically treated 10 asthmatic patients and obtained mixed results. Sessions consisted of hypnotic suggestions for easier breathing, lessening of tension and bronchiospasms, and an increase in self-confidence. Drug consumption and respiratory function as well as self-report were all assessed. Patients were rated in terms of depth of hypnosis achieved. Results varied depending on the particular measure used. Physiological measures indicated that improvement followed after 24% of the treatment sessions, whereas self-report of improvement followed 62% of the trials. Subject improvement was independent of the depth of hypnosis achieved.

Maher-Laughan (1970) reported three investigations that included autohypnosis training and hypnotic suggestions of a release in tension, an increase in self-confidence, and a belief in the possibility of recovery. In the first study, 55 patients were randomly placed in either a relaxation and breathing exercise control group or in a hypnosis and autohypnosis training treatment group. Change was assessed in terms of a computed wheezing score and in the number of times bronchodilators were used. Greater improvement was noted in the hypnosis treatment group. The second study included a larger number of patients who were treated by a greater number of centers and added a physiological assessment of respiratory function. Whereas males reported similar improvement in both the hypnosis group and the control group, females reported less improvement in the control group. The hypnosis group showed greater improvement on the physiological assessments of forced expiratory volume. Self-report and physiological indices were independent of the type of asthma treated (psychological, infectious, or allergic). The third study was similar to the first two except that patients were preselected for treatment, and a control group was not employed. In this investigation, 82% of the

patients improved. Duration of treatment was 6 months, 1 year, and 6 years, respectively, in the three studies, with few or no treatment effects recognized earlier than 1 month into treatment.

The greatest number of controlled studies on the largest number of subjects has been carried out with asthmatic patients. The methodological sophistication of these studies far exceeds the studies of skin disorders or headaches. Effectiveness of hypnotic treatment appears to be a function of which outcome measures are employed. When self-report is used, most investigators report an improvement in the patient's symptoms. However, physiological measures show more equivocal results.

Discussion and Conclusions

Of the 38 studies reviewed, 31(81.6%) reported overall positive results, 5(13.1%) reported negative outcomes, and 2(5.3%) reported mixed results. Eighteen (47.4%) were single- or multiple-case studies, 13(34.2%) used a single treatment group, and 7(18.4%) instituted necessary control conditions. All of the single- and multiple-case studies resulted in a positive outcome. Ten single treatment group studies yielded a positive outcome, 1 yielded a negative result, and 2 yielded a mixed outcome. Three of the 7 controlled studies resulted in a negative outcome. Apparently when methodological shortcomings were remediated, the effects of hypnosis were reduced.

There were 1,189 subjects/patients in the 37 studies that reported sample size. (Kroger, 1963, did not report the number of patients treated.) Single- and multiple-case studies involved only 35 patients (2.9% of the total) even though case studies constituted almost half of the studies reviewed. Studies obtaining positive results involved 1,037(87.2%) subjects/patients. Only 152 (12.8%) subjects/patients were involved in studies that yielded negative or mixed results.

A comparison of the three disorders shows that 67.3% of the patients were asthmatic, 23.4% were headache patients, and 9.2% had skin disorders. Inspection of Table 1 reveals that hypnosis was most successful for asthmatics; all but two studies in Table 1 used at least a treatment group. Results were positive in 11, negative in 2, and mixed in 2 studies. For headaches, 5 out of 9 were case studies, and 1 of the only 2 controlled studies yielded negative results. Only 3 out of the 14 studies of skin disorders used at least a treatment group. The 2 controlled studies yielded negative results.

Changes in autonomic nervous system functioning (i.e., blood flow, skin temperature, forced air capacity) are thought to serve as mediators of symptomatic changes. Twenty-three (60.5%) studies used hypnosis in an attempt to directly affect physiological change (i.e., the blood flow to the skin will decrease). In only 8 of these 23 studies was there an attempt to assess these changes. Four of the 8 reported negative results.

Four (10.5%) of the studies used hypnosis to help the patient gain insight. All reported success, but this was based on self-reports or physicians' impressions, and no objective measure of success was reported.

Of 10(26.3%) studies, in which hypnosis was used to alter patients' perceptions of their disorders, 8 reported successful outcomes, and 2 reported mixed results.

Physiological or objective indices were used in only two studies of skin disorders, with negative results. Understandably physiological or objective measures were not used in the headache studies because headache pain is almost exclusively a subjective experience. Vasoconstriction and muscular tension have been found to correlate with headache pain and could have been used. In the asthma studies, 11 used a physiological or objective measure. Positive outcomes were reported in 7, and negative results were reported in 4 studies. A much higher rate of success was found for the 32 studies using self-report as a measure. All outcomes but 1 were positive.

It appears the attempts to alleviate symptoms by suggesting direct and specific physiological changes through hypnosis has met with some success, as measured by self-report, but results that used objective or autonomic measures have been equivocal.

None of the investigations of headache attempted to assess muscular or vascular changes. The studies of skin disorders as-

sessed the physical changes in the skin. However, mediating physiological changes such as blood flow and skin temperature were generally not monitored. The change in symptoms (disappearance of warts, changes in pruritus, etc.) cannot be taken as evidence for direct physiological change due to hypnosis. Controls were not sufficiently applied to show a cause and effect relationship between the applications of the hypnotic procedures and the alleviation of symptoms. Evidence from the asthma studies supports the contention that hypnosis does not produce physiological changes as consistently as it produces self-reported and observed changes. This is in agreement with arguments presented by Barber (1974) who contends that "the data available at present do not support the notion that hypnotic trance is a critical factor in producing such physiological effects" (p. 70).

There seems to be some anecdotal evidence that alleviation of symptoms may be aided by using hypnosis to help patients to gain insight into the development and maintenance of their symptoms. A difficulty with these investigations is a lack of an established cause and effect relationship between insight and symptom remission. The possibility of spontaneous remission or placebo effects was not controlled for in these case studies.

Evidence exists for the claim that when hypnosis is used to alter the perceptions of psychosomatic symptoms, headache and asthma patients report symptom improvement. This appears to be especially useful either in disorders in which the perception of the symptoms themselves is the primary concern (i.e., tension headaches) or when the disorder is being treated by an additional treatment regime and symptomatic relief is desirable.

Future researchers, in addition to stating the ultimate goal of the hypnotic intervention, also should clearly specify the mediating physiological mechanisms for the expected change. The precise role of these mechanisms could then be systematically assessed.

Controls should be instituted in this research for suggestions alone, hypnosis alone, and physician and patient interaction. In this way, the role of these variables could be separately assessed. In addition, the possibilities of spontaneous remission of symptoms and placebo effects, which seem to occur with great frequency in psychosomatic disorders, should be controlled.

Researchers should assess hypnotic susceptibility using a well-established scale. Although some researchers have argued for the placement of subjects into groups based on their susceptibility, this procedure would limit the extent to which a cause–effect relationship could be inferred between treatment and outcome. A more useful procedure would be to randomly place subjects, regardless of their susceptibility scores, into treatment groups while simultaneously monitoring the effects of susceptibility on outcome.

In spite of the many methodological problems, there was some indication of the usefulness of hypnosis as a treatment adjunct for psychosomatic disorders. This is particularly true for asthma, the disorder on which the best research has been done and for which the most promising results obtained.

Stimulus Overselectivity in Autism: A Review of Research

O. Ivar Lovaas
University of California, Los Angeles

Robert L. Koegel
University of California, Santa Barbara

Laura Schreibman
Claremont Men's College

Infantile autism is a severe form of psychopathology characterized by profound behavioral deficits. This article reviews a series of investigations which suggest that autistic children show "stimulus overselectivity," a response to only a limited number of cues in their environment, and discusses how such overselectivity may relate to several of the behavioral deficits in autism. These include failure to develop normal language or social behavior, failure to generalize newly acquired behavior to new stimulus situations, failure to learn from traditional teaching techniques that use prompts, and a general difficulty in learning new behaviors. This discussion is followed by the presentation of several studies that suggest possible remedial procedures. Finally, the concept of stimulus overselectivity is related to the literature on other theories of attentional or response deficits in adult schizophrenia, mental retardation, learning disabilities, and autism.

Infantile autism, first described by Kanner (1943), is a severe form of psychopathology in children that is characterized by extreme social and emotional detachment. Such children typically do not seek or readily accept affection and do not play with peers. They engage in great amounts of stereotyped, ritualistic, and repetitive motor behaviors and are generally unresponsive to their physical environment. They are inconsistent in their response to sensory input, they typically do not show a startle reflex, and their parents have suspected them to be blind or deaf. Language development is either absent or abnormal, and those autistic children who do speak usually parrot meaninglessly what they hear (echolalia). Another characteristic feature of autism is the child's insistence on order and sameness in his or her environment. When one considers the behavioral impoverishment of these children, it is understandable that autism is also characterized by a poor prognosis.

In recent years, numerous studies have appeared that somewhat alter the prediction of a poor prognosis. For example, autistic children who are treated within a learning theory framework (with "behavior modification") have shown measurable improvement in speech and language (e.g., Hewett, 1965; Lovaas, 1966, 1977; Risley & Wolf, 1967), generalized imitation (Lovaas, Freitas, Nelson, & Whelan, 1967; Metz, 1965), and appropriate play (Koegel, Firestone, Kramme, & Dunlap, 1974), as well as reduction of inappropriate behaviors (e.g., Carr, Newsom, & Binkoff, 1976). A comprehensive summary of these and other studies has been provided by Lovaas and Newsom (1976). However, in spite of considerable successes, there are still a number of problems associated with this

The preparation of this article and portions of the research reviewed were funded by U.S. Public Health Service Research Grants MH 11440, MH 28210, and MH 28231 from the National Institute of Mental Health and by U.S. Office of Education Research Grant G007802084 from the Bureau for the Education of the Handicapped.

The authors wish to gratefully acknowledge the administration and staff of Camarillo State Hospital, Camarillo, California, for their assistance and cooperation in the collection of much of the data reported here.

form of intervention. Two important problems are that the treatment effects may be situation specific and reversible, and the child's progress in treatment is slow (Lovaas, Koegel, Simmons, & Long, 1973).

Problems in situation specificity of the treatment change and in reversibility of treatment effects can be attenuated somewhat by extending the treatment across time and situations, by, for example, using parents and teachers as therapists (e.g., Schreibman & Koegel, 1975). However, there has been no immediate solution to the slow rate of improvement that these children show in treatment. It may be most helpful, therefore, to discuss certain mechanisms that may be basic to this problem of attenuated change, with a view toward the development of faster and more general changes. Towards this end, this article will review a set of studies that provide substantial evidence which suggests that autistic children have a problem in responding to multiple cues, and that this problem may be at least part of the cause of their slow improvement in treatment.

Situations in which several cues impinge simultaneously on children are typical of those they encounter in their everyday teaching environments. Operationally, our data show that when autistic children are presented with multiple stimulus inputs, their behavior comes under the control of a range of input that is too restricted. This problem was referred to as "stimulus overselectivity" (Lovaas, Schreibman, Koegel, & Rehm, 1971) because the children overselected a limited set of stimuli from those available in their environment. Note that the term *stimulus overselectivity* does not imply that the children scan their environment and select for relevant cues. Rather, the data suggest that the children respond to only part of a relevant cue, or even to a minor, often irrelevant feature of the environment, without learning about the other relevant portions of that environment.

Our approach to this analysis in autistic children owes much to the conceptual and methodological advances of basic operant research, as first reviewed by Terrace (1966) and later extended by Ray (1972), Ray and Sidman (1970), Sidman and Stoddard (1966), and Touchette (1968, 1971). Basically, the studies we report adhere to a discrimination learning paradigm, permitting us to simply relate aspects of the manipulated stimulus input directly to the child's behavior. Excellent reviews of this type of research have also been provided by Fellows (1968), Sutherland and MacKintosh (1971), and Trabasso and Bower (1968).

This article first reviews a set of studies demonstrating stimulus overselectivity, and then presents data that show how such overselectivity may interfere with the autistic child's learning and pose problems for the generalization of learned material. This will be followed by suggestions on how this problem might be remedied. Finally, the concept of stimulus overselectivity will be related to other theories of attentional deficits in autism and related disorders.

Studies Demonstrating Stimulus Overselectivity

Overselective Response to Multiple Cues

In the Lovaas et al. (1971) study, autistic, retarded, and normal children were taught to respond to a complex stimulus display (S^D) containing three elements: (a) a moderately bright visual stimulus (consisting of a 160-W red floodlight), (b) an auditory stimulus consisting of white noise at a moderately high (65-dB level) intensity, and (c) a tactile stimulus on the child's leg delivered by a pressure cuff at 20 mm of mercury. These stimuli appeared noticeable to the children, since they often oriented to them (e.g., turned around to look at the light, touched their legs when the cuff was inflated). This complex S^D was presented to the children, and they were reinforced for responding (bar pressing) in the presence of the display and not reinforced for responding in its absence. After training had established this stimulus display as functional for the children's response, single-cue test trials were presented in which each component (auditory, visual, tactile) was presented separately for a total of 70 presentations over 10 test sessions.

The results showed that the normal children responded to each of the components equally. In other words, each of the separate cues became equally functional in controlling the

child's behavior. The performance of the autistic children was different. Each child responded primarily to only *one* of the component cues. (The retarded children responded at a level between these two extremes.) Three of the autistic children responded primarily to the auditory component, whereas two of the children responded primarily to the visual cue. None of the autistic children responded to the tactile stimulus. It was striking to observe the autistic children attentively respond to one of the component cues (e.g., the sound), only to remain motionless in the presence of the other (e.g., the light) even though that stimulus had been presented as discriminative for reinforcement.

Subsequently, two of the autistic children were trained to respond to the component that had remained least functional for them during test sessions. Both children quickly learned to respond to the previously nonfunctional component, *when that component was presented alone.* This helped to ensure that the problem was not one of some relatively "simple" sensory deficit (as in the case of being blind or deaf) but was rather a problem in responding to the cue in the context of other cues.

It was concluded from this first study that the data could best be understood as representing the autistic child's difficulty in responding to stimuli in context, a problem pertaining to the quantity rather than to the quality of stimulus control. The data failed to support any notion that a particular sense modality was impaired in autistic children or that any particular sense modality was a "preferred" modality.

Overselective Response to Two Cues

Since the autistic child may have been "flooded" or "overloaded" with stimulation in the first study, a second study (Lovaas & Schreibman, 1971) was conducted in which the stimulus input was simplified: The child was presented with only two cues. The two cues were the same red floodlight and white noise used in the previous study. The experimental paradigm was also the same as in the previous study.

It may be of interest to examine the data from this study in some detail, since they show certain unpredictable peculiarities. The six normal children tested gave no signs of stimulus overselectivity; they responded equally to the two components when these were presented on separate occasions during test trials. It was different with the autistic children. The data are presented in Figure 1. Four of the children showed the stimulus overselectivity most clearly. For each of these children only one of the cues was functional in controlling their behavior. Two of these children (Kevin and Michael) displayed some response to both component cues during early parts of the testing but eventually lost rather than acquired the response to the nondominant cue. The fifth and sixth children (Janet and John T.) showed stimulus overselectivity in the early test trials but gradually began responding to the initially weak component cue as testing progressed. They may have overcome their overselectivity with testing. Another child, Jimmy, showed control by one of the stimuli at first (the visual one); but as testing progressed, for some reason the visual stimulus lost its control, whereas the auditory stimulus gradually assumed control. Bobby showed only a slight case of stimulus overselectivity, if any. Finally, the last child, John P., responded equally to both components and showed no evidence of stimulus overselectivity.

Thus stimulus overselectivity was not observed for all the autistic children in this study, whereas all of the children gave evidence of stimulus overselectivity in the previous study, which involved three cues. It may be that stimulus overselectivity is most clearly observed with a relatively larger quantity of stimulus inputs.

Discrimination of a Complex Stimulus From Its Components

Several questions can be raised as to why the autistic children responded the way they did on these tests. One possibility is that autistic children have a genuine difficulty in responding to the separate components of a complex input. Another possibility is that autistic children do respond to the components

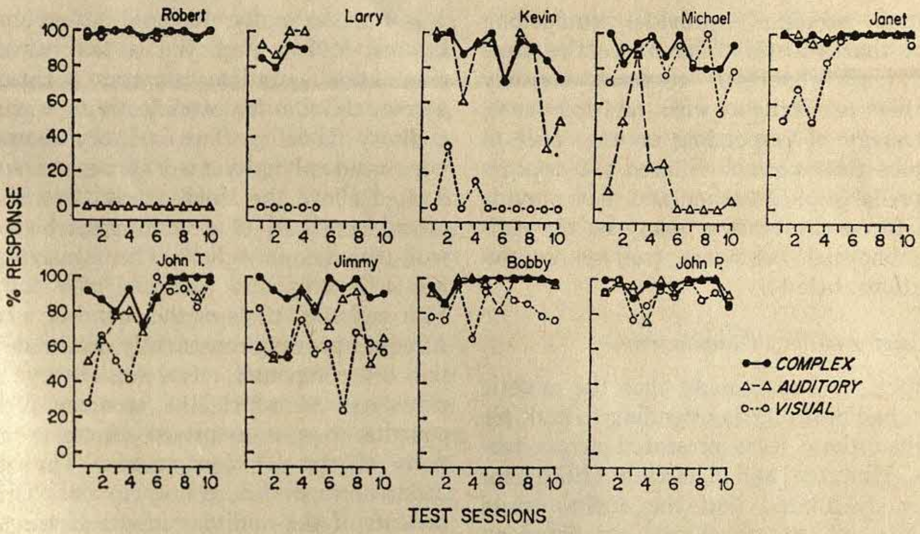

Figure 1. Test sessions for the autistic subjects. (Percentages of correct responses to stimuli are plotted on the ordinate, and test sessions are plotted on the abscissa.)

but that they are "superefficient," so that they immediately know (discriminate) that it is enough to respond to only one component of a complex input to be reinforced. They may exert minimum effort for maximum payoff.

Koegel and Schreibman (1977) conducted a study to help answer these questions. The procedures and apparatus were similar to those employed in the first two studies. Subjects were first trained to respond to the separate presentations of an auditory and then a visual stimulus. That is, the components were presented first. At the completion of the training phase the child was presented with either the separate cues or these cues combined in a complex. Thus, three types of trials were presented: visual only, auditory only, and visual and auditory combined. All responses to the complex auditory–visual input were reinforced, whereas responses to either of the single cues were not reinforced.

The most general conclusion to be drawn from the results of this study is that in this conditional discrimination task, autistic children experienced great difficulties discriminating the complex stimulus from its components. This conclusion is based on the fact that the autistic children continued to respond to *one* of the components, for hundreds of trials, even though they were not reinforced for doing so; concurrently, their response to the other (also nonreinforced) cue extinguished relatively rapidly. In contrast, the normal children extinguished on both of the single nonreinforced components quickly and simultaneously. Since the autistic children continued to respond to one of the single components, even though such responding was not reinforced, it does not seem likely that stimulus overselectivity shown by autistic children is based on some variable such as efficient responding. To respond consistently to one, and only one, of the nonreinforced components as well as to the reinforced stimulus complex seems like a fairly complicated strategy, unless one postulates that the complex and one of the components were difficult to discriminate from each other. It may also be important to note that the autistic children did eventually extinguish responding to both component cues. Thus, it appears that the autistic children were attempting to learn the discrimination but had difficulty doing so.

Another major point of this experiment is that with a completely different experimental paradigm, the same type of result was obtained as in the other studies. That is, the consistency in the results across all of these experiments (regardless of the specific ex-

perimental paradigm) provides compelling evidence that autistic children use the same specific (and abnormal) response strategy when they are taught with multiple cues. This strategy of responding on the basis of fewer cues than normal children use appears to be a reliable phenomenon and may provide a basis for understanding many of the children's abnormal behaviors (see section on Implications, below).

Visual and Auditory Overselectivity

Initially, we had thought that the autistic children had difficulty in attending to multiple cues when these were presented across modalities. Hintgten and Churchill (1971), for example, speculated that the autistic child may have an attentional problem based on some difficulty with "integrating" information along more than one modality. Subsequent studies in our laboratory suggest that autistic children have difficulty with multiple cues even when these cues are presented within the same modality.

Koegel and Wilhelm (1973) trained 15 autistic children and 15 normal children of approximately the same chronological age on a visual discrimination task. Their procedure followed the relevant redundant cue paradigm. The children were trained to discriminate between two cards, each card containing two visual cues. After the children had mastered this discrimination (consistently responding to one of the cards), test trials were conducted in which the visual cues on the cards were split so that one of the components of the correct card was presented versus one of the components on the incorrect card. The autistic children gave evidence of overselective responding in this situation by reliably choosing a card with one of the components of the original complex correct stimulus and responding at chance level to the other component. The normal children, on the other hand, responded predominantly to both the components during testing. At an even finer level of analysis, Koegel and Schreibman (1977) found that low-functioning autistic children show visual overselectivity even between the components of a single visual stimulus, such as selectively responding to the color, form, or shape of a triangle.

In another study, Reynolds, Newsom, and Lovaas (1974) employed a successive discrimination paradigm to test autistic and normal children for overselectivity within the auditory modality. Two auditory compounds were randomly presented through a speaker located above the child's head. The S^D compound consisted of a continuous high tone, with periodic relay clicks. The negative stimulus (S^Δ) compound consisted of a low tone with periodic bursts of the sound of a motor. After bar pressing consistently occurred during the S^D compound, test sessions were administered in which the separate S^D components were interspersed among presentations of the S^Δ components. The normal children responded reliably to both S^D components of the auditory input. However, the autistic children responded to one S^D component, giving evidence for stimulus overselectivity within the auditory modality.

The studies reviewed above are consistent with studies from other laboratories which suggest that autistic children have particular difficulties when they are expected to associate multiple stimuli. For example, Cowan, Hoddinott, and Wright (1965) found that only 2 of 12 autistic children were able to associate simple shape or color words with corresponding visual stimuli. Bryson (1970) noted that autistic children performing match-to-sample tasks disregarded extra visual stimuli when they made vocal responses. Similarly, Frith and Hermelin (1969) found that if normal children were blindfolded during maze training tasks, they were relatively more handicapped than when autistic children were blindfolded. Apparently, the autistic children were less affected by additional cues than were the normal children.

Stimulus Overselectivity, IQ, and Mental and Chronological Age

Although the preceding studies suggest that autistic children show stimulus overselectivity, one must remain skeptical about the role of such overselectivity in the etiology of autistic behavior for at least two reasons. First, since these studies provide correlational data only, stimulus overselectivity could just as well be the effect of autistic behavior as its cause.

Second, in the studies we have described so far, a few autistic children showed little or no evidence of overselectivity, whereas some children who were not autistic did overselect. For example, in the Lovaas et al. (1971) study discussed previously, retarded (but nonautistic) children did overselect.

A relationship between IQ level and stimulus overselectivity was demonstrated in a study by Wilhelm and Lovaas (1976) that reported on three groups of children with different IQ levels. On a discrimination task that could be solved by the child attending to either one, two, or all of three component cues, the low IQ (20) group responded on the average to 1.6 cues, the higher IQ (40) group responded to 2.1 cues, and the normal IQ children responded to all three cues.

A similar finding has also been reported on the relationship between chronological age and stimulus overselectivity. Schover and Newsom (1976) found that the younger the children, the more likely they were to show overselectivity. The Schover and Newsom findings are in accord with other studies that show a positive correlation between number of cues responded to in the visual discrimination task and mental age in normal and retarded children (Eimas, 1969; Fischer & Zeaman, 1973; Hale & Morgan, 1973; Olson, 1971).

It remains to be determined whether this general finding that relates mental age to overselectivity will hold up with multimodal stimuli, as in the first studies presented here (Lovaas & Schreibman, 1971; Lovaas et al., 1971). Until studies employing such stimulus compounds are carried out, the status of overselectivity as an etiological factor in autism remains in doubt; as Schover and Newsom (1976) and Sivertsen (1976) have pointed out, young normals showing visual overselectivity seem intuitively to be far ahead of their autistic counterparts in linguistic, intellectual, affective, and social behaviors. Nevertheless, autistic or retarded children who remain overselective long after their normal peers have moved beyond this mode of functioning are clearly at a disadvantage in acquiring new behavior, and overselectivity undoubtedly contributes to the maintenance of such children's behavioral retardation (Ross, 1976; Wilhelm & Lovaas, 1976). That is, the more limited the aspects of the environment become in controlling the children's behavior, the more retarded will be their behavioral development. This conclusion will become apparent when we discuss the relationship of overselectivity to learning situations that require shifts in stimulus control and the generalization of acquired behaviors across environments.

Implications

Some of the implications of these findings for understanding autistic development seem obvious and were pointed out in an earlier article (Lovaas et al., 1971). We argued that many learning situations in life necessitate responding to multiple cues. Speech, for example, is a complex stimulus input for which adequate responding necessitates the child's attention to a number of stimulus dimensions (e.g., voiced vs. voiceless, tense vs. lax, volume vs. pitch). If a child responds to only one or two of these dimensions, he or she will not understand what is said. Reynolds et al. (1974) speculated that autistic children's deficiency in language may be based on their failure to respond to multiple inputs. Similarly, much of the meaning in language involves associating multiple inputs, as in associating language cues to a variety of sensory inputs such as sight and feel. We also speculated that stimulus overselectivity may underlie autistic children's deficiency in emotional behavior. Thus we pointed out that classical conditioning is considered by many to underlie the acquisition of emotional behavior. The latter requires attention to two or more contiguous or nearly contiguous stimuli (the conditioned and the unconditioned stimulus). In such a situation autistic children may well overselect, responding to one or the other of these stimuli, but not both. If they fail to respond to both, they may fail to condition (Maltzman & Raskin, 1965).

In the following section we try to support with data some of these speculations on how stimulus overselectivity interferes with autistic children's learning and with the generalization of that learning to new environments.

Observational Learning

Undoubtedly, many of the complex and subtle behaviors that are shown by normal children are learned by watching social interactions of various kinds (Bandura, 1969). Children who do not naturally learn in this way can be expected to show considerable behavioral retardation. Observational learning seems to be an area in which autistic children are particularly handicapped, and their failure to learn through observation may well be basic to one's understanding of their behavioral deficiencies (Ross, 1976). Typically, observational learning necessitates attention to multiple cues, in observing both a model's behavior and the consequences of that behavior.

Varni, Lovaas, Koegel, and Everett (1979) obtained data which suggest that stimulus overselectivity may prevent observational learning in autistic children. In this study, the autistic children sat at a table across from two adults (a model and a teacher). On the table in front of them rested two objects, each of which was used in the execution of an associated response. The investigators assessed the extent to which the children could learn how to behave in this situation by merely observing the model handle the objects in accordance with the teacher's instructions. The teacher gave the model a command (e.g., "phone"), and the model then behaved accordingly (e.g., picked up the handset of the phone) and was rewarded by the teacher. A sequence of 20 observation trials was followed by one test trial to see if the children had acquired the task. During the test trials the children took the model's seat and were given the same command by the teacher. Correct performance on a test trial was taken to indicate that observational learning had occurred, since the children were not directly taught by the teacher to respond correctly. The observation trials continued until the children responded correctly on a test trial, or until they had experienced 1,000 trials without showing evidence of learning. If this first task was mastered, a second response that involved a second object was presented (e.g., placing a ball in a toy dump truck when the teacher said "dump"); and if tests showed that the children mastered both responses, they were given 10 additional test trials with the two verbal commands presented in random order.

Data from this study showed that the autistic children usually learned only part of the response they observed. For example, a child might touch rather than pick up the phone or merely touch or move the dump truck. In some cases the children learned the complete behavioral topography but did not associate it with the teacher's verbal command. For example, a child might pick up the phone regardless of whether the teacher said "phone" or "dump." In summary, the children's failures could be related to their responses to only restricted portions of the complex stimulus situation that they had observed.

Prompt Studies

Another kind of learning in which stimulus overselectivity seems particularly handicapping is in the area of prompting and prompt fading. Prompts are usually extra stimuli added to the learning situation to ensure correct responding. In this kind of learning a teacher may help the children associate a response to a particular stimulus by first prompting the right response. Many learning situations involve such prompts or "guidance" because the teacher may not be able to wait for the children to give the correct response on their own. For example, in teaching children to read a new word, the teacher may prompt them by also presenting a picture of the referent. If such learning is to be successful, such prompting or guidance must eventually be removed or "faded" so that the children behave on their own. Technically, such learning is referred to as the acquisition of *stimulus control*, and involves shifts in stimulus control from prompt stimuli (e.g., picture) to training stimuli (e.g., written word).

The stimulus overselectivity hypothesis suggests that the provision of additional stimuli in prompt procedures may prevent the children from learning. That is, most prompt procedures require the children to respond to multiple cues (the prompt and training stimuli occur together) and should create situations in which stimulus overselectivity is likely to occur.

Koegel and Rincover (1976) provided data that show the deleterious effects on learning when extra cues are used as prompts. They pretrained autistic and normal subjects to respond differentially to two easily discriminable colors (red and green). Once this discrimination was mastered, the colors were used as prompts and presented simultaneously with more difficult discriminations. (e.g., A low-pitched tone was presented concurrently with the color red and a high-pitched tone with the color green.) The colors were then eliminated gradually, the auditory stimuli alone remaining. The normal children learned the new (e.g., tone) discrimination this way, whereas the autistic children usually failed to transfer from the prompt to the training stimuli. Instead they continued to respond to the color cues even when they were faded to a barely recognizable level. However, the autistic children did acquire these new discriminations when prompts were not used in training. The Koegel and Rincover data suggest that the use of extra cues may make it more difficult for the autistic children to learn. Schreibman (1975) observed the same problem. The autistic children responded selectively to the prompt as long as it was available but reverted to chance performance when the prompt was removed.

Such problems with prompts may happen more often when the discrimination involves difficult rather than easy discriminations, as shown in a study by Russo (Note 1). He reported that autistic children shift from a prompt (finger pointing) to training stimuli more readily when the task is easy (e.g., black vs. white) than when it is difficult (e.g., vertical line vs. a slightly tilted line).

Generalization Studies

Restrictions on the number of stimuli that acquire control over behavior could cause serious problems in stimulus generalization, that is, the extent to which a behavior learned in one environment transfers to other new environments. This relates to the familiar problem of "undergeneralization" of therapeutic gains—the failure of a behavior, acquired in a therapeutic setting, to transfer to a new "outside" environment.

One can consider generalization to take place to the extent that there are common stimulus elements between the teaching situation and outside situations. Amount of generalization, then, may vary proportionately with the number of stimulus elements that controlled the behavior initially. The fewer the stimuli that had become functional in the original situation, the fewer stimulus elements that would control the behavior in the new environment; hence limited generalization occurs. This latter problem, that of limited generalization, has been clinically observed in all our work with autistic children. It is shown in a study by Rincover and Koegel (1975), in which stimulus overselectivity seemed to directly limit generalization. In this experiment, one teacher taught autistic children to perform a simple behavior on request (e.g., "touch your nose"). Immediately after each child had learned this behavior, a second teacher took the child into another environment and made the same request. Four of the 10 autistic children did not perform the relatively simple behavior in the new environment. Extensive single-subject analyses showed that those four children had failed to generalize the learned behavior because they had selectively responded to irrelevant stimuli during the original training and had not learned the response on the basis of the relevant cue. In one case, for example, the child's responding was controlled by incidental movements of the teacher's hand, and not by the relevant verbal cue. (i.e., Without the incidental hand movement the child would not respond to the verbal cue, whereas the child would respond to the hand movement either alone or with the verbal cue.)

Note that this result is different from saying that the autistic children responded to too many cues (i.e., central plus incidental cues; cf. Tarver, Hallahan, Kauffman, & Ball, 1976). Rather, the autistic children responded to too few cues so that in some instances, they responded only on the basis of an incidental cue and not on the basis of the central cue; thus it appeared as if they failed to generalize when they were in environments in which the incidental cue was absent. Subsequently, when the second teacher simply introduced the incidental cue (e.g., raised a hand in a

similar way) in the outside setting, the children did generalize appropriately. That is, generalized responding occurred only after the systematic exploration and isolation of the controlling stimuli in the treatment environment and the introduction of these specific stimuli to new (outside) environments.

Another study, designed to help understand the autistic child's problem with generalizing social stimuli, can also be understood as a problem caused by stimulus overselectivity. Specifically, Schreibman and Lovaas (1973) taught normal and autistic children to discriminate between lifelike male and female figures (dolls). Subsequent tests showed that normal children distinguished between the figures on the basis of a number of cues, including the figures' heads; but autistic children used only some minor and unreliable feature, such as the figures' shoes, and did not respond to reliable cues such as the figures' heads. For example, when the investigators removed the shoes from the figures after a child had learned to tell the figures apart, the child suddenly lost the discrimination, only to regain it in additional training by using an equally unreliable feature. Parents of autistic children often report that even a minor change in their (the parents') appearance, such as a mother cutting her hair or the father removing his glasses, may cause an abrupt change in their child's behavior, such as treating the parents as strangers or responding with major emotional upheaval. Perhaps the problem autistic children have with stimulus overselectivity contributes to their social aloofness in the presence of the complex, multidimensional stimuli provided by human beings.

Remedial Treatment

Within-Stimulus Prompts

The studies described above may help to explain why autistic children fail to develop adequately. The main strength of these studies, however, lies in the guidance they provide in construction of more therapeutic environments for such children. For example, the autistic child's problems with situations that involve prompts may lead to the design of therapeutic learning environments that prevent the deleterious effect of such prompts. The therapist or teacher may avoid situations in which the autistic child would overselect a nondistinctive (i.e., irrelevant) stimulus element and thereby fail to learn the discrimination. Two recent studies investigated the possibility of preventing the development of such unintended stimulus–response relationships. They employed procedures designed to establish control by the distinctive feature of the correct stimulus at the start of training and to maintain this control while irrelevant features were gradually faded in.

In the first study, Schreibman (1975) wanted to teach autistic children the difference between form stimuli that were difficult to tell apart. A child's everyday environment abounds with difficult form discriminations, such as the difference between people who smile and frown, a heater dial being turned on and off, letters like *b* and *d*, and so on. Normal development seems to require the acquisition of such discriminations. In one of the discriminations employed by Schreibman, the children were required to identify one of two very similar stick figures, shown in Figure 2. The figures were identical except that one had an arm raised, whereas the other had both arms down. Thus, the only relevant component of the discrimination was the orientation of the arms; all other components were redundant. The child was asked to point to the "correct" figure. For the purposes of this experiment, for some of the children the figure with the raised arm was designated correct; for others the other figure was correct. The autistic children failed to learn this discrimination even though the teacher went through extensive and elaborate prompting procedures, such as carefully pointing to the correct stimulus and then gradually removing the pointing cues. The autistic children did learn to discriminate between increasingly fine "finger points," but did not transfer their response from the teacher's finger to the stick figures. Schreibman then used a different prompt procedure that involved altering and exaggerating the relevant component of the discrimination (arm orientation) and prompting within the same stimulus dimension as the training stimulus. Figure 2 illustrates this procedure. The children were initially pre-

sented with two cards. One card was blank, and the other card had a heavy diagonal line across its surface. Step 1 of Figure 2 shows this discrimination. As the children learned this discrimination, size cues were gradually faded out (see Figure 2) until the children were responding to the line orientation (relevant cue). Then, the redundant components of the discrimination (head, body) were slowly faded in. Using this within-stimulus prompt fading procedure, the autistic children learned the discrimination that they had failed to learn with traditional prompting. The main difference in procedure was that the within-stimulus prompt did not require the children to respond to multiple cues, since the prompt was within the training stimulus.

Rincover (1978) extended Schreibman's work with an analysis of four visual fading procedures and their effectiveness in teaching autistic children discriminations between three-letter words. Two variables were assessed: (a) distinctive versus nondistinctive feature fading, which signified whether a prompt was a feature contained only in the S^D or contained in both the S^D and S^Δ, and (b) within- versus extrastimulus fading, which signified whether the prompt was superimposed on the S^D during fading or presented spatially separate from the S^D. The four fading procedures were all combinations of these two variables. As expected, the combination of distinctive-feature and within-stimulus prompting was most effective in teaching the discriminations. It was suggested that this success was due to the fact that response to the stimulus component first encountered in training was all that was required of the child; this component was never removed during the fading progression and was still available in the criterion discrimination. Thus, neither response to multiple cues nor a shift in stimulus control was necessary, as they were in the other three training procedures.

Multiple-Cue Training

Techniques such as those suggested by Schreibman (1975) and Rincover (1978) work around the overselectivity problem by constructing learning environments that allow the child to remain overselective, yet learn. However, it may also be possible to work directly on the overselectivity problem, assuming it is not permanent but itself amenable to learning. In our clinical work, as in the work of others (e.g., Risley & Wolf, 1967), autistic children eventually learned to "use" extrastimulus prompts rather than always be hindered by them. Although the exact reasons for this were not evident in the clinical work per se, the results of recent research suggest that overselectivity may be modifiable.

Schover and Newsom (1976) directly attacked the problem of overselectivity by training autistic children to broaden their

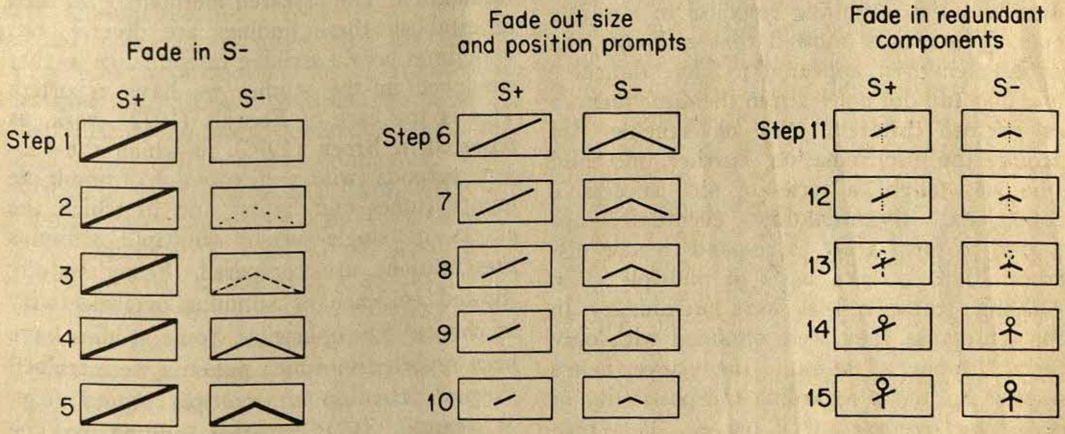

Figure 2. The within-stimulus prompt and fading steps used to teach discrimination between two stick figures. (Adapted from "Effects of Within-Stimulus and Extra-Stimulus Prompting on Discrimination Learning in Autistic Children" by L. Schreibman, *Journal of Applied Behavior Analysis*, 1975, *8*, 91–112. Copyright 1975 by the Society for the Experimental Analysis of Behavior, Incorporated. Reprinted by permission.)

responding to include multiple cues. They examined the effects of overtraining an already learned discrimination between simple figures (such as a large green square and a small orange triangle). Their data showed that overtraining increased the number of cues responded to by autistic children. They concluded that the overselectivity shown by autistic children is probably not the result of a permanent disability, or that it may be permanent but treatable, like diabetes.

A study by Schreibman, Koegel, and Craig (1977) further strengthens this inference. Using discrimination tasks, they found that simple overtraining (just exposure) did not help the autistic child to respond to more cues. However, prolonged testing with unreinforced probe trials interspersed among reinforced training trials eliminated overselective responding in 13 of 16 autistic children who were initially overselective. That is, children who selectively responded to one of the two available cues early in testing eventually responded to both cues as test trials continued. Since all of the stimuli in this study were in the visual modality, it is possible that the rapid reduction in overselectivity was a function of the stimuli used.

In perhaps the most direct attempt to test the hypothesis that overselectivity could be modified, Koegel and Schreibman (1977) taught five autistic children a conditional discrimination requiring response to multiple cues. The results showed that although the autistic children appeared to have difficulty learning and did not learn in the same manner as normal children, they nevertheless did acquire the discrimination. Further, one child who was taught a series of nine successive conditional discriminations eventually appeared to form a set to respond to new discriminations on the basis of multiple cues. Although these results were preliminary in the sense that they were obtained with only certain types of stimuli, they nevertheless suggest optimism regarding the possibility of correcting overselectivity per se. This possibility has numerous implications. Perhaps the most important are that (a) if overselectivity were eliminated, autistic children might be more likely to benefit from more traditional teaching procedures that typically require such responding, and (b) elimination of overselectivity may enable the children to respond to their environment in a more normal manner and thus facilitate large-scope, rapid changes in behavior.

These studies on eliminating the deleterious effects of stimulus overselectivity suggest that such overselectivity may be overcome or taken advantage of, as the situation requires, if sufficient effort and imagination are used in teaching autistic children. The findings provide basis for optimism that an experimentally derived technology for successfully teaching autistic children could be forthcoming.

Relation to Adult Schizophrenia, Learning Disabilities, and Mental Retardation

The discussion of overselective responding in autism shows a striking similarity to certain research on adult schizophrenics. Researchers in the area of adult schizophrenia typically distinguish between acute and chronic schizophrenics on the basis of breadth of cue utilization. Acute schizophrenics are described as responding to too many cues in their environment. They are not able to select out the relevant stimulation to the exclusion of the irrelevant. In contrast, chronic schizophrenics are more like autistic children in that they respond to a limited amount of available stimulation. The research methodologies used to establish these findings are diverse, but sometimes bear a striking resemblance to that employed in the studies we have reported. This is the case of Feeny's (1972) work, as reported in Broen (1973), in which the subject responds (with a microswitch) to multiple inputs (tones and lights) and in which the effects of single versus multiple stimulus presentations are compared. Feeny's study showed evidence of stimulus overselectivity in chronic schizophrenics. Some studies have been reported in which patients were trained to pay attention to multiple inputs (e.g., Meiselman, 1971), further adding to the similarity in our approaches. Broen's (1973) description of the findings on limited or narrowed attention in chronic schizophrenics seems relevant to the research we have

reviewed on autism:

> Chronic schizophrenics do indeed show a narrower range of cue utilization than normals or acute schizophrenics. Their ability to note and respond to relevant cues is especially impaired when the cues are located in more than one sensory modality. (p. 207)

In the same article, Broen speculates on the effects of such restricted responding:

> A life style dedicated to limiting stimulation . . . increases the likelihood of a *chronic* inability to monitor the environment and adjust to its changing demands . . . [it] maintains the potential for disorganization in the face of complexity. (p. 193)

If we consider the fact that many autistic children become diagnosed as chronic schizophrenics as adults, then our data may help to better understand the process of chronic schizophrenia. This seems particularly true if one assumes that children with a less complex history would show such problems as underlie schizophrenia in a more "pure" form. In any case, it seems striking as well as encouraging that two independent areas of investigation have produced such similar findings and reached such similar conclusions; one must, however, exercise considerable caution in drawing inferences common to adult chronic schizophrenia and autism, considering the problems in diagnosis and the diversity in research methodology. Other reviews of the literature on cue utilization and schizophrenia have been provided by Lang and Buss (1965), McGhie and Chapman (1961), Silverman (1964), and Venables (1964).

The concepts discussed here also appear similar to those discussed in the literature on learning disabilities in children. People in this field discuss auditory dominance (e.g., Senf & Treundl, 1971), visual dominance (Baker & Raskin, 1973; Gaines & Raskin, 1970), and sensory integration (e.g., Baker & Raskin, 1973; Birch & Belmont, 1964; Chalfant & Scheffelin, 1969). Indeed a great deal of research in this area points to defective attention as central to learning disabilities (e.g., Dykman, Ackerman, Clements, & Peters, 1971; Luria, 1961; Ross, 1976; Senf & Treundl, 1971; Strauss & Lehtinen, 1947; Trabasso & Bower, 1968; Zeaman & House, 1963). The possibility exists, however, that the results applicable to learning disabled children may not be directly comparable to the results with autistic children because of the many definitions of "learning disabled" and because of different methods of investigation. For example, Tarver et al. (1976) reported that some learning disabled children may be underselective and respond to too many cues. However, Ross (1976) has pointed out several similarities between the difficulties manifested by autistic children and certain learning disabled children when required to respond to cross-modality multiple cues. He reviews several studies supporting this interpretation (e.g., Vande Voort, Senf, & Benton, 1972).

In the area of mental retardation, investigators such as Zeaman and House (1963) have carried out extensive studies on various aspects of discrimination learning and have concluded that deficits in response to multiple cues may be a crucial factor in the poor performance of such children. When these investigators compared children of various levels of retardation, they found that the lower level retarded children took longest to learn. However, there were no differences between children in learning rates once improvement began. That is, rather than very slowly and gradually acquiring a discrimination, the more severely retarded children showed no increases in correct responding for many trials and then suddenly showed large increases in correct responding, at the same rate as normal children. The difference between the high- and low-level children was in how many trials they took before they started to show increases in correct responding. These investigators also found that they could shorten the number of trials it took the low-level children (i.e., decrease the differences between high- and low-level children) by directing their attention to a relevant cue in the task. The general conclusion drawn from experiments such as these has been that retarded children take a long time to learn because their attention is not focusing on a relevant aspect of the discrimination but that once they attend to a relevant cue, they can learn as fast as normal children. Relating this conclusion to our results, we would speculate that the reason retarded children take so long to attend to a relevant cue is that they are sampling (responding to) fewer cues at a time than normal children, and therefore the

probability is lower that a relevant cue will be included in any given sample.

Relation to Other Work on Attentional Problems in Autism

Attentional abnormalities have been suspected by many authors on autism as the basic problem in the etiology of that disorder. The attentional problem is well illustrated in Kanner's (1944) description of one of his patients:

> When spoken to, he went on with what he was doing as if nothing had been said. Yet one never had the feeling that he was willingly disobedient or contrary. He was obviously so remote that the remarks didn't reach him. (p. 212)

The clinical literature on autism abounds with similar descriptions, as when the parents suspect the child may be blind and deaf only to be puzzled at observing that sometimes their child can see and hear quite well. For example, the child may not respond to his or her name being called or startle at a loud sound like a slamming door, but may respond to a barely audible siren or the sound of candy being unwrapped. Koegel and Schreibman (1976) tell of a child who showed this inconsistency in responding to a remarkable degree. It may be this inconsistency or variability in responding that has led people to infer that the autistic child has a deficiency in perceptual or attentional mechanisms rather than a sensory deficit.

The following is a brief discussion of the major theories that have been advanced to account for the attentional deficits in autism. It is surprising how many of these theories postulate some restriction in attention, analogous to the stimulus overselectivity hypothesis that we have proposed, as basic to autistic development.

Psychodynamic Theories

Psychodynamic theorists presented the first attempt to account for the autistic child's unresponsivity, seeing such unresponsiveness as a defense against a hostile, threatening world. For example, Bettelheim (1967) proposed that autistic children narrow the range of their attention because they feel it necessary to shut out of awareness their disappointing, unresponsive, and destructive parents. It seems clear that the psychodynamic orientations talk of restricted or narrowed attention in the autistic child and that this is seen as a defense against interpersonal trauma.

Empirical research designed to investigate attentional deficits based on social trauma has provided little support for the psychodynamic formulations. For example, Hermelin and O'Connor (1963) studied autistic and retarded children (matched on IQ) in a free-field situation designed to assess the amount of attention to visual, auditory, manipulative, or social stimuli and found no significant difference between the groups in the amount of attention to the different stimuli. In a later study O'Connor and Hermelin (1963) found no evidence of autistic withdrawal from social stimuli. These same investigators (O'Connor & Hermelin, 1967) compared visual fixations of normal, severely retarded, and psychotic children to two simultaneous card displays depicting social (faces) and nonsocial stimuli. They found that (a) compared to the other groups, the psychotic children spent less time looking at any display cards and more time in nondirected gazing, and (b) all children, including psychotics, looked more at a picture of a face than at the scrambled pictures of the same face. Similar findings are reported by Young (1970). Thus, the experimental evidence does not lend support to the notion that autistic children display a particular attentional deficit in relation to social stimuli.

Developmental Theories

Developmental theories of perceptual deviations in autism are based on observations of animal and normal human development (Sherrington, 1906; Zaporozhets, 1961), and hold that there is a normal transition from preference and dependence on the near receptors (tactile, kinesthetic, gustatory) in early life to the dominance of input from the far receptors (visual, auditory) in later life. It has been postulated that the autistic child's unresponsiveness to auditory and visual stimulation is due to a failure in development beyond the near-receptor stage (Goldfarb, 1956; Schopler, 1965).

Some data are consistent with this model. For example, Pollack and Goldfarb's (1957) data suggested that autistic children were not making good use of added visual cues. Frith and Hermelin (1969) presented additional evidence consistent with these findings. They studied normal, autistic, and retarded children to compare the relative use of visual and tactile cues. For example, in one experiment the children were tested on three tasks. One task could be solved on the basis of visual cues only. The second task could be solved by either visual or tactile cues or both. The third task could only be solved using tactile cues. They found that all children did better with the visual cues except the developmentally backward autistic children. For them, providing visual information had no facilitatory effect. Goldfarb and Braunstein (1958) presented similar data, as in their report that normal children's speech was disturbed while listening to delayed auditory feedback and the speech of childhood schizophrenics was unaffected.

Schopler (1966) found that normal and retarded subjects showed a higher preference for visual stimulation than did the schizophrenic subjects. (Normals and schizophrenics were matched on chronological age [CA], retardates and schizophrenics on mental age [MA].) He also found that normal subjects increased in their visual preference with age. Similarly, Hermelin and O'Connor (1964) presented psychotic and normal children of the same MA and CA with stimuli in different modalities and found that the psychotic children responded much more often to touch and the normal children to sound.

But much empirical research has failed to support the developmental model of sensory deficit. In Schopler's (1966) study he did not find a difference between the normal, retarded, and schizophrenic subjects in their preference for tactile cues, nor did he find that the normals decreased in their preference for tactile stimulation with age. Also, the retarded subjects in that study showed an increase in tactile preference with a decrease in visual preference with increase in MA. Both these findings are difficult to fit into a developmental interpretation. Also, Goldfarb (1961) found no significant difference in the abilities of normal and schizophrenic children in relation to visual, auditory, and tactile cues. In the Hermelin and O'Connor study (1963) cited earlier, autistic and retarded children did not differ in their responsiveness to visual, auditory, and tactile stimuli. The same investigators (O'Connor & Hermelin, 1965) failed to confirm their earlier (Hermelin & O'Connor, 1964) findings of near-receptor preference in autistics. Finally, in our own studies (e.g., overselective response to three cues and to two cues) we failed to observe the autistic's preference for a particular stimulus hierarchy. The autistic subjects responded on the basis of either visual or auditory cues, and none of them responded to the tactile (near-receptor) cue.

In general, the literature on developmental receptor preferences does not provide a tenable explanation of sensory deficit in autism. But the data do support the notion that autistic children may act like a developmentally immature organism in their restricted response to multiple cues. Perhaps developmental variables may sometimes be understood as related to "breadth of cue use" independent of sensory preferences.

Arousal Theories

Several theories of sensory dysfunction in autism have emphasized the physiological mechanisms related to arousal. Since the level of physiological arousal is an important determinant of how much the organism will be affected by environmental stimulation, it is reasonable to postulate that pathological mechanisms influencing arousal would interfere with normal sensory processes. There are three basic arousal theories represented in the literature. One position suggests that autistic children suffer from a chronically low level of arousal, another suggests a chronically high level of arousal, and the third postulates alternating periods of high and low arousal.

The main proponent of the underarousal theory is Rimland (1964). He hypothesized that autistic children are chronically underaroused because of a dysfunction of the reticular activating system. A stage of underarousal would account for the child's restricted attention to external stimulation. Rimland's use (pp. 201–204) of "narrow bands" (from

information theory) seems particularly close to our use of stimulus overselectivity in accounting for the behavioral peculiarities of autism. Metz (1967) provided some data consistent with the underarousal hypothesis. He found that when autistic and normal subjects were allowed to control the volume of an auditory stimulus, the autistics preferred higher levels of stimulation than did the normals. But in general the underarousal theory has little direct supporting evidence and has not been subjected to rigorous empirical investigation.

The overarousal hypothesis is based on more empirical findings. Hutt, Hutt, Lee, and Ounsted (1965) hypothesized that in autistic children the nonspecific activity of the reticular activating system is sustained at a high and relatively inflexible level. They point to the possibility that the typical unresponsiveness displayed by autistics is a defensive function preventing excessive arousal. Hutt, Hutt, Lee, and Ounsted (1964) suggested that the overarousal hypothesis is also consistent with the desire for sameness in the environment. Novelty leads to increased arousal and is thus avoided. Some support for the overarousal position is provided by Connell (1966), who observed that autistics often require higher than normal doses of sedative drugs. Rutter (1968) described two important problems with an overarousal theory. First, level of arousal may be related to level of maturation or development. The Hutt et al. (1965) subjects were matched on CA but not MA. Thus it is possible that the lower MA of the autistics accounts for the differential electroencephalogram (EEG) patterns of the two groups. Second, high arousal may have developed as a secondary rather than a primary defect. Hermelin and O'Connor (1968) found no major differences in alpha rhythm in the EEGs of autistic, Down's syndrome, and normal children in several conditions differing in amount of sound and light stimulation. Only when continuous noise was present in one of the conditions did the autistics display relatively more arousal than the other groups. This suggests that overarousal may be a secondary response to environmental stimulation.

A third arousal theory is the "perceptual inconstancy" hypothesis offered by Ornitz and Ritvo (1968). According to this theory, there is a specific pathological process that begins in the first year of life when there is a failure of the central nervous system (CNS) to develop adequate homeostatic regulation of sensory input. Without control over incoming sensory stimulation, the child experiences random overloading and underloading of the CNS. At it is now formulated, the perceptual inconstancy hypothesis does not relate clearly to our work on stimulus overselectivity. Although both viewpoints address the problem of selective attention, our data suggest that the autistic children responded to only one stimulus component (auditory or visual) in a complex stimulus and that they responded to that same component consistently day after day. If, as Ornitz and Ritvo say, the underloading and overloading of the CNS is random, we should not have observed such consistent patterns of responding.

Other Relationships

Much may be learned by relating the studies on stimulus overselectivity more closely to similar work with animals. A thorough review of that work is beyond the scope of this article, but it should be mentioned that Pavlov noted in 1927 that the conditioned response to one element of a complex stimulus was as large as the response to the complex, leaving the response to the other elements negligible. Similar early references to the distinction between "nominal" and "functional" or effective stimuli can be found in the work of Harlow (1945) and Warren (1953). Reynolds (1961), for example, trained two pigeons to discriminate between two white forms on differently colored backgrounds (red or green). It was found that one pigeon responded only to the white form and the other pigeon responded only to the colored background. Some persons have considered the underlying mechanism behind selective responding to be genetic (some cues are more dominant for some species than others). Other persons have attributed selective responding to prior learning of one cue, which then "blocks" (as in "stimulus blocking") or inhibits responding to other cues that are also

available. Perhaps animal studies may provide information about the basic cause of (over) selective responding.

Conclusion

Looking across all of these studies, one can make several general observations. It is apparent that under a wide range of different testing situations, low-level autistic children come under the control of an extremely restricted range of stimuli. At this point, however, it may be premature to label this phenomenon in other than a descriptive manner. Thus we have chosen to employ the term *stimulus overselectivity*, rather than other more inferential terms such as *association deficiency* or *deficiency in selective attention*. There are, however, many parallels between our results and those discussed in the discrimination learning literature in the area of selective attention.

We are limited in our inferences regarding the mechanism behind the phenomenon, but we are still able to relate the children's overselective responding to a number of their abnormalities. Specifically, we have reviewed findings relating overselectivity to deficiencies in (a) generalization, (b) the use of "extra-stimulus" prompts, (c) language learning, (d) social behavior, and (e) observational learning. We have also been able to relate overselectivity to specific remedial procedures. For example, the work on prompting has resulted in an extremely efficient technique (within-stimulus prompting) for teaching at least some behaviors. Our major observation, and our main point in this article, is that overselectivity frequently occurs in children diagnosed as autistic, that this characteristic can be reliably measured, and that a knowledge of its existence may be useful in planning for these children's education and treatment.

Two-Sample T^2 Procedure and the Assumption of Homogeneous Covariance Matrices

A. Ralph Hakstian, J. Christian Roed, and John C. Lind
University of British Columbia, Vancouver, Canada

Results of an empirical investigation of the robustness of Hotelling's two-sample T^2 test with respect to violation of the assumption of homogeneity of covariance matrices are presented. Empirical sampling distributions of the T^2 statistic were obtained from a large number of sets, each consisting of 2,000 samples drawn from multivariate normal parent populations. Average sample size (n), extent of inequality of sample sizes, number of variables (p), and degree of inequality of covariance matrices were combined into 108 different conditions. Actual proportions of values that exceeded nominal α levels are presented. For equal ns, the procedure is shown to be generally robust. With unequal ns, the procedure is shown to become increasingly less robust as covariance matrix heterogeneity and p increase. The results are related to earlier findings, and implications for the proper use of the T^2 procedure are noted.

Hotelling's (1931) two-sample T^2 procedure for multiple dependent variables is widely used in the behavioral sciences today, being the uniformly most powerful test in the case of two-group p-variate simultaneous comparison (Anderson, 1958, pp. 115–118). Textbooks dealing with multivariate statistical methods in the behavioral sciences (e.g., Harris, 1975; Morrison, 1976; Tatsuoka, 1971), however, typically provide the reader with at most a brief treatment of the robustness of the method. The one investigation that is often referred to is that of Ito and Schull (1964), who investigated the large-sample properties of the distribution of T^2, showing analytically that for equal and large sample sizes, heterogeneity of covariance matrices has no substantial effect on the probability of Type I error.

Although infrequently referred to, several studies on this topic have been conducted. Two articles other than Ito and Schull's (1964) contain analytical results: Mardia (1971), who examined the effects of multivariate nonnormality (in the face of which the multivariate analysis of variance [MANOVA] class of tests is relatively robust), and Pillai and Sudjana (1975), who examined the effects of covariance matrix heterogeneity on four test criteria. Although limited to the bivariate case, small ns, and unclear degrees of heterogeneity, their results showed modest departures from nominal α values for minor degrees of heterogeneity and more pronounced departures with greater heterogeneity.

Several empirical Monte Carlo studies have dealt with the robustness of the T^2 test. Chase and Bulgren (1971) examined nonnormality, an issue not dealt with in the present article. Hopkins and Clay (1963) examined heterogeneity of covariance matrices, although only for the bivariate case. Olson (1974), who compared six MANOVA criteria, dealt with only the equal-n case. These studies provided some insights into the robustness of the T^2 test, although none illuminated the issue fully.

One reasonably comprehensive empirical study was that by Holloway and Dunn (1967), who, in general, found that with equal ns and a fairly large ratio of subjects to dependent variables, the T^2 test is robust. As expected,

The research reported in this article was supported in part by Grant A9088 from the National Research Council of Canada.

The authors gratefully acknowledge the advice of Ingram Olkin during the execution of the study.

with unequal *ns*, the test was found to be less robust being conservative, when the larger sample was drawn from the population with generally greater dispersions, and liberal in the opposite situation. The main defect in this study, however, at least for the present purposes, was the unrealistically different heterogeneity conditions (e.g., variables in Population 2 that had variances 10 or 100 times those in Population 1) and unequal-n conditions that were not disparate enough ($n_1:n_2$ ranging from 15:35 to 35:15). In addition, for $n_1 \neq n_2$, $n_1 + n_2$ was fixed at 50, thus preventing the systematic examination of overall sample size as a factor in the issue of robustness.

Although something is known therefore about the robustness of the T^2 test, it is not so clear at what degree of departure from optimal conditions (equality of sample *ns*, homogeneity of covariance matrices, etc.) the procedure manifests an unacceptable actual α level. The purposes of the present study were (a) to examine simultaneously all independent variables relevant to robustness so that a comprehensive picture of each of these variables could be obtained, in terms of both their main effects and their possible interactive effects; (b) to represent the independent variables so that they represented real-world behavioral data in terms of levels that are identifiable with characteristics of observable data variables; and (c) to distill the results necessary to provide guidelines for the proper use of the T^2 procedure in psychological research.

The Monte Carlo Investigation

Independent Variables

Sample size. To assure comparability among data sets with different numbers of variates, the ratio of average sample size, $(n_1 + n_2)/2$, to number of variates was manipulated. Two ratios were used: 3 subjects per variable and 10 subjects per variable.

Inequality of sample sizes. The ratios of the sizes of the two samples were also varied. Three such ratios were used: 1:1, 2:1, and 5:1.

Number of variables. Three levels of this factor were used: 2, 6, and 10.

Heterogeneity of covariance matrices. This factor was central in the present study. Heterogeneity of population covariance matrices can, of course, arise from many causes and in a vast number of forms and degrees. It seems true, however, that the most obvious occurrence of such heterogeneity is that in which a sample that is drawn from a population with normal dispersions of the variables is compared with one that is either implicitly or explicitly selected or restricted in some way.

In the present study, the authors attempted to generate data that would possess the same heterogeneity often found in real-world data by introducing scale factors in four ways:

1. The variables in Population 2 were rescaled by 1.2, that is, whereas the variables in Population 1 were all set with $\sigma = 1$, those in Population 2 had σs of 1.2 and thus σ^2s of 1.44. This can be seen as a mild departure from homogeneity and is referred to as Heterogeneity Condition 1.
2. The variables in Population 2 were rescaled by 1.5. This scaling (Heterogeneity Condition 2) represented a moderate to substantial degree of heterogeneity. The Population 2 variances and covariances were thus 2.25 times those for Population 1.
3. The first $p/2$ variables in Population 2 were of the same scale as those in Population 1, whereas the last $p/2$ variables were rescaled by 1.5. Heterogeneity Condition 3 represented the situation of selection on some but not all of the variables.
4. The variables in the two populations were in precisely the same scale, that is, no rescaling took place. This is, of course, the homogeneity condition.

Population 1 covariance matrices (Σ_1) were constructed for the three p levels, 2, 6, and 10. These Σ_1 matrices appear in Table 1. Population 2 covariance matrices for each value of p (Σ_2) were then obtained by $\Sigma_2 = \mathbf{D}_i\Sigma_1\mathbf{D}_i$, where $i = 1, \ldots, 4$, and where the diagonal $\mathbf{D}_i$ matrices contained the scale factors referred to above. Thus, for Heterogeneity Conditions 1 and 2, $\mathbf{D}_1$ and $\mathbf{D}_2$, respectively, contained 1.2 and 1.5 in each diagonal position. For Heterogeneity Condition 3, $\mathbf{D}_3$ contained 1 in the first $p/2$ diagonal positions and 1.5 in the last $p/2$, and for the homogeneity condition, $\mathbf{D}_4$ was simply $\mathbf{I}_p$.

Table 1
Population Covariance Matrices Used in the Study as Σ_1

2 variables: Variable	1	2
1	100	
2	50	100

6 variables: Variable	1	2	3	4	5	6
1	100					
2	40	100				
3	30	35	100			
4	40	25	10	100		
5	30	40	50	30	100	
6	20	30	00	40	15	100

10 variables: Variable	1	2	3	4	5	6	7	8	9	10
1	100									
2	40	100								
3	30	50	100							
4	50	30	30	100						
5	40	40	50	20	100					
6	20	20	40	50	40	100				
7	10	40	00	30	30	50	100			
8	20	30	50	10	50	30	40	100		
9	30	20	30	20	30	20	50	30	100	
10	50	00	10	40	10	40	30	00	20	100

Note. Entries are actual values multiplied by 100. The Σ_2 matrices that were used in the study were obtained from those in Table 1 by means of rescalings described in the text.

Previous treatments, such as those of Ito and Schull (1964) and Pillai and Sudjana (1975), have operationalized covariance matrix heterogeneity in terms of the diagonal matrix of latent roots yielded by the product $\Sigma_2\Sigma_1^{-1}$. Using the scheme for generating covariance matrix heterogeneity noted previously, it can easily be shown that since $\Sigma_2 = \mathbf{D}_i\Sigma_1\mathbf{D}_i$, the eigenstructure of $\Sigma_2\Sigma_1^{-1}$ or, equivalently, of $\mathbf{D}_i\Sigma_1\mathbf{D}_i\Sigma_1^{-1}$ contains a diagonal matrix of latent roots equal simply to $\mathbf{D}_i^2$. In Heterogeneity Conditions 1 and 2, these roots will, of course, all be equal.

Relationship between heterogeneity and inequality of sample size. This concerns whether, when $n_1 \neq n_2$, the larger sample was drawn from the population with larger dispersions (the positive condition) or smaller dispersions (the negative condition). Thus this two-level factor was not fully crossed with all other factors: It did not apply when $n_1 = n_2$ or when $\Sigma_1 = \Sigma_2$.

Summary of the independent variables studied. From the preceding, it can be seen that in all, 108 conditions were examined—90 conditions in which $\Sigma_1 \neq \Sigma_2$ [$2 \times 3 \times 5$ (2 positive $n_1{:}n_2$, 2 negative $n_1{:}n_2$, and 1 equal) $\times$ 3] and 18 in which $\Sigma_1 = \Sigma_2$ ($2 \times 3 \times 3$). An understanding of the overall design of the study will be facilitated by examination of Tables 2, 3, and 4, which appear later in the article.

Data Generation

The generation of sample data was accomplished by random number generation on the University of British Columbia IBM 370/168 computer. Independent uniformly distributed random numbers on the interval (0, 1) were generated and then transformed to normally distributed random numbers with mean 0 and variance 1 by Marsaglia's rectangular-wedge-tail method (Knuth, 1968). Strings of length Np (where $N = n_1 + n_2$) of such independent random normally distributed data points were generated and then partitioned into two data sets X (one, n_1 subjects by p variates, the other n_2 subjects by p variates). With the string partitioned in this way, each $n_j \times 1$ ($j = 1, 2$) variate vector was normally distributed, with mean 0 and

Note. Each proportion is based on 2,000 pairs of samples. The various conditions involve Σ_1 and Σ_2 and magnitude and departure from equality of n_1 and n_2.
[a] The degree of heterogeneity present is discussed in the text.
[b] The $n_1:n_2$ ratios are such that they represent, as closely as possible, three levels: 1:1, 2:1, and 5:1.
[c] The positive condition refers to that in which the population whose covariance matrix contains the larger entries is that from which the larger n is drawn, where $n_1 \neq n_2$. The negative condition is that in which the population whose covariance matrix contains the larger entries is that from which the smaller n is drawn. For situations where $n_1 = n_2$, this dichotomy does not, of course, exist, and entries in Table 2 are given between the Positive and Negative columns.

variance 1 and was independent of every other vector. It can easily be demonstrated that the joint distribution thus arising is MVN(0, **I**) (see, for example, Anderson, 1958, pp. 19–27).

So that each data matrix **Y** would represent a sample from a population with a known covariance matrix Σ, the following transformation was applied. The desired population covariance matrix was first canonically decomposed as $\Sigma = \mathbf{V}\Lambda^2\mathbf{V}'$, and a "factor" matrix **F** was obtained by $\mathbf{F} = \mathbf{V}\Lambda$. Next, the $n_j \times p$ MVN(0, **I**) data matrices **X**, described previously, were postmultiplied by $\mathbf{F}'$, yielding $\mathbf{Y} = \mathbf{XF}'$. This process can be considered to produce a sample data matrix that could have arisen from a population having covariance matrix Σ, since

$$E(\mathbf{Y}'\mathbf{Y}) = E[(\mathbf{XF}')'(\mathbf{XF}')] = E(\mathbf{FX}'\mathbf{XF}')$$
$$= \mathbf{F}E(\mathbf{X}'\mathbf{X})\mathbf{F}' = \mathbf{FF}' = \mathbf{V}\Lambda^2\mathbf{V}' = \Sigma.$$

In this way, 2,000 pairs of samples (from populations in which the null hypothesis was

true) were generated for each of the 108 conditions studied. For each pair of samples, the T^2 statistic was computed and transformed to a value (F), which under a true null hypothesis is distributed as a central F variate with degrees of freedom p and $(n_1 + n_2 - p - 1)$. The obtained F values were then compared to the 90th, 95th, and 99th percentile points of the appropriate F distribution, and the percentage lying above those points was tabulated for each condition.

Results

The results of the described Monte Carlo analyses appear in Tables 2, 3, and 4; each table deals with a separate p value (2, 6, or 10). The tabled proportions, based as they all are on 2,000 sample pairs, are subject to mild sampling error and should be interpreted accordingly. Using the standard error of a proportion and normal curve probabilities, we can set approximate .95 confidence intervals

	.10	.107	.026	.241	.003	.484	.055	.311

Note. Each proportion is based on 2,000 pairs of samples. The various conditions involve Σ_1 and Σ_2 and magnitude and departure from equality of n_1 and n_2.
[a] The degree of heterogeneity present is discussed in the text.
[b] The $n_1:n_2$ ratios are such that they represent, as closely as possible, three levels: 1:1, 2:1, and 5:1.
[c] The positive condition refers to that in which the population whose covariance matrix contains the larger entries is that from which the larger n is drawn, where $n_1 \neq n_2$. The negative condition is that in which the population whose covariance matrix contains the larger entries is that from which the smaller n is drawn. For situations where $n_1 = n_2$, this dichotomy does not, of course, exist, and entries in Table 4 are given between the Positive and Negative columns.

around each nominal α value tabled as (a) .10 ± .013, (b) .05 ± .010, and (c) .01 ± .004. Thus, any value between, for example. .040 and .060 can be considered to be within sampling error of the nominal value of .050.

The results for the two-variable case appear in Table 2. We see, first, that the robustness of the T^2 test with equal ns extends to relatively small samples. As expected, the test is unaffected by inequality of ns with equal Σs. When sample sizes are unequal, however, and $\Sigma_1 \neq \Sigma_2$, the actual α level can differ considerably from nominal, falling below nominal in the positive case ($n_2 > n_1$) and exceeding it in the negative ($n_1 > n_2$). With the $n_1:n_2$ ratio fixed, the degree of departure from the nominal α level increases as the degree of inequality of covariance matrices increases. Also, with the degree of covariance matrix heterogeneity fixed, the degree of discrepancy between actual and nominal α values increases as the $n_1:n_2$ ratio departs from one. And in-

creasing the sample size while maintaining the ratio between the two sample sizes does not help; if anything, the reverse is true.

Tables 3 and 4 contain the results for, respectively, the 6- and 10-variable conditions. All of the earlier results generalize to conditions involving more variables. Again for a fixed $n_1:n_2$ ratio and degree of Σ heterogeneity, actual α values tended to be more discrepant for the larger average sample sizes than for the smaller.

Examination of Tables 2, 3, and 4 reveals that with an increase in the number of dependent variables, p, the effects of these factors on the statistical test become more pronounced, in spite of the fact that the ratio of average sample size to number of variates was held constant (3:1 and 10:1). In the most extreme cases reported here, the departure from nominal α levels became large indeed, as is seen, for example, in Table 4.

Conclusions

From these results, it is clear that the T^2 procedure is generally robust with respect to violation of the homogeneity of covariance matrix assumption for equal sample sizes, even when the ratio of sample size to number of dependent variables is small, for example, three subjects per variable. Under these conditions, the T^2 procedure has been shown to be able to withstand population scale differences of 1.5 on all variables (Heterogeneity Condition 2)—with the number of such variables as large as 10—a scale factor that implies a between-populations variance difference of 2.25, a difference that seems like a realistic extreme for behavioral data. Holloway and Dunn (1967) demonstrated that with massive population variance differences (e.g., 10:1 on all variables), sample size equality does not uniformly produce a robust test with samples smaller than about 50, although the number of variates is relevant, since situations that involve two or three variates show robustness at ns of 25, but those that involve 10 do not become robust until about $n = 100$. For $n_1 \neq n_2$, however, the test moves rapidly towards unacceptable Type I error rates as the degree of population covariance matrix heterogeneity is increased. Even for relatively mild between-populations dispersion differences and particularly as p becomes larger, a sample size ratio of even 2:1 produces unacceptable actual α values. With greater heterogeneity, the 2:1 $n_1:n_2$ ratio yields values that are completely out of hand, which is also true for the case of mild heterogeneity but more severely unequal ns (5:1). Also important is the fact that these results appear to be independent of sample size. In summary, it is clear that the T^2 procedure is not robust in the face of covariance matrix heterogeneity coupled with unequal ns, even for relatively mild departures from equality of the covariance matrices, sample sizes, or both.

Implications for Proper Use of the T^2 Procedure

It seems clear that prior to the T^2 analysis, the sample covariance matrices $\mathbf{S}_1$ and $\mathbf{S}_2$ should be inspected and inferentially tested for equality. The homogeneity issue has implications for not only the T^2 test but also for discriminant analysis—often employed to supplement T^2 results—in which heterogeneous covariance matrices, in the two-group case, suggest a quadratic rather than a linear function (Rao, 1965, pp. 488–489).

Statistical tests of the hypothesis of equal covariance matrices have been available for many years, with Bartlett's (1947) modification of the likelihood ratio criterion and Box's (1949) improved chi-square and F approximations (see Harris, 1975, pp. 85–86). These procedures, however, have been shown to be extremely sensitive to multivariate nonnormality (Hopkins & Clay, 1963; Mardia, 1971). Although little is known about it, a newer procedure due to Layard (see Timm, 1975, pp. 252–253) may be more robust in this regard.

Clearly, the user of the T^2 procedure is almost certainly on safe ground if the two samples have equal ns. There is little chance that a Type II error in the homogeneity test will cause a seriously biased test of the central hypothesis. Greenstreet and Connor (1974) showed that even for small (and equal) ns, scale differences in the variables of from 2 to 3 were detectable with high probability. And as noted, only for huge variance differences (e.g., 10:1) is the T^2 test biased. Thus, re-

jection of the homogeneity hypothesis will probably not be serious with equal *n*s.

With equal *n*s and rejection of the equality-of-covariance matrix hypothesis, the question remains of whether in a given instance the T^2 test is likely to be biased. As demonstrated, an operationalization of heterogeneity is the magnitude of the latent roots of the product $\Sigma_2\Sigma_1^{-1}$. Given a strict rescaling of the variables, these elements are the variance ratios of the variables. For sample data, therefore, if $\mathbf{D}$ with diagonal elements d_{ii}, is the diagonal matrix of latent roots of $S_2S_1^{-1}$ (such that $\Pi_i^p d_{ii} > 1$), then $(\Pi_i^p d_{ii})^{1/p}$ is a sample estimate approximately equal to a squared scaling factor, or an approximate overall estimated variance ratio. If this value is less than 5, for example—as will generally be true of real-world psychological data—then the user can safely ignore the inequality of the covariance matrices and proceed with the T^2 analysis. For larger *n*s—50 or beyond, for example—the T^2 will be sufficiently robust with heterogeneity values (as noted) of up to 10. Thus, the user can ascertain whether rejection of the homogeneity hypothesis is relevant for the T^2 analysis; as demonstrated, such a rejection will usually be irrelevant.

It is when $n_1 \neq n_2$ that problems arise. If the test of covariance matrix homogeneity is nonsignificant, no problem exists; but if this test is significant, the user is faced with the multivariate extension of the Behrens-Fisher problem. The following strategy—in the order of steps listed—seems to be a reasonable approach.

1. Ascertain whether one is in the positive or negative condition. A direct assessment of this comes from comparison of the determinants (understood as generalized variances) of S_1 and S_2. If either $n_1 > n_2$ and $|S_1| > |S_2|$ or $n_1 < n_2$ and $|S_1| < |S_2|$, we have the positive condition, whereas if the opposite obtains, we are in the negative condition. It is, of course, possible for $|S_1|$ to be equal to $|S_2|$, although $S_1 \neq S_2$. In such a case, however, the above taxonomy does not apply, and the effects of such heterogeneity may not be serious.

2. Given the positive condition, the T^2 test will be conservative. Thus the user should run the test and, if it is significant, reject the null hypothesis a fortiori.

3. Given the negative condition, the T^2 test will be liberal. Thus the user should run the test and, if it is nonsignificant, retain the null hypothesis.

4. If in the positive condition, T^2 is nonsignificant or if in the negative condition, T^2 is significant, two possibilities exist: (a) If the *n*s are not extremely different, they can be equalized by random deletion of subjects from the larger group. If in fact the null hypothesis is false, the loss of power may not be too great, and the previously significant T^2 (negative condition) may still be significant. The previously nonsignificant T^2 (positive condition) may now be significant. (b) If the *n*s are substantially different so that equalization would result in a massive loss of power or if the equalization performed when *n*s are not extremely different results in nonsignificant results, the user can employ one of several solutions to the multivariate Behrens-Fisher problem—reasonably precise approximations that do not require deletion of subjects. Such solutions can be found in an article by Ito (1969).

Cerebral Electrotherapy: Methodological Problems in Assessing Its Therapeutic Effectiveness

Carmen L. von Richthofen
Memorial University of Newfoundland, St. John's, Newfoundland, Canada

Clive S. Mellor
Department of Psychiatry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada

Cerebral electrotherapy (CET) appears to offer a safe and comfortable method of treating a variety of conditions, principally anxiety, depression, and insomnia. Attempts to assess its therapeutic efficacy have yielded widely differing results. This may be attributable to considerable variation in the electrical characteristics of the apparatus used, the duration of the treatment, and the placement of the electrodes. In some double-blind studies, the placebo condition has differed significantly from the treatment, and in most the ideal situation with a blind machine operator, subject, and assessor, has not been achieved. Until the methodology for assessment improves and the treatment procedure is standardized, it will be impossible to determine if CET is an effective treatment, and if it is, whether its mode of action is attributable to a direct effect on the brain or to relaxation, suggestion, or tactile stimulation.

Reports from Eastern Europe and particularly the Soviet Union suggest that cerebral electrotherapy (CET) or electrosleep treatment, holds considerable promise in the treatment of a variety of conditions. This review examines the methodological problems that have attended controlled studies that attempt to validate these claims. First, an overview of what the term CET implies is provided.

Overview

Electrosleep, or cerebral electrotherapy (CET), is a somatic therapy characterized by the passage of a low-amplitude, pulsating direct electrical current around and through the cranium. Originally, electrosleep was intended to induce a state of natural sleep, "a state of consciousness grossly indistinguishable from ordinary sleep, produced by the direct action of a weak rhythmic current on the brain of a cooperative subject in a nondistracting environment" (Boblitt, 1969, p. 9).

Requests for reprints should be sent to Clive S. Mellor, who is also at the St. Clare's Mercy Hospital, St. John's, Newfoundland, Canada A1C 5B8.

Pavlov is said to have provided the concept and rationale for electrically produced sleep therapy (Boblitt, 1969; Obrosow, 1959). His concept of cerebral protective inhibition was based on the idea that a prolonged, monotonous, weak stimulus, such as a mild pulsating electric current, which is applied to the central nervous system under conditions of comfort, allows the brain cells to rest and permits restoration of function.

Investigations into the effects of direct electrical currents have been going on since the 19th century. Included in the techniques was that of electroanesthesia, or the depression of consciousness, a state determined by the basic criterion of nonresponsiveness to pain and achieved by means of an electric current usually in the range of 20 Hz to 1 KHz (Brown, 1975). A second technique, polarization, resembles and is often confused with CET. The major differences involve the use of constant rather than pulsating current and the positioning of electrodes on the arm or leg rather than solely on the cranium. Polarization is thought to be useful in producing mood changes (Lippold & Redfearn, 1964).

The modern view of electrosleep therapy as a technique distinct from electroanesthesia

began with the Soviet researcher Giljarowskii in the early 1950s (Lewis, 1966).

The view that the sole purpose of electrosleep therapy was to induce a sleeplike state to promote functional recovery of cerebral cells influenced the type of research carried out in the Soviet Union and Europe. Most of this research has been presented at the International Symposia for Electrosleep and Electroanesthesia, first held in 1966, with subsequent meetings in 1969 and 1972. It was after the first symposium that the notion of a therapeutic, protective, artificial sleep was gradually replaced by the idea that the direct action of the current itself was the healing force:

> Our experience has shown that sleep in the course of the individual session is not an absolute condition of success of therapy . . . . The passage of the pulse current through the brain is of greater importance for a curative effect than the achievement of the condition of sleep in one course of treatment. (Van Poznak, 1969, p. 507)

Accordingly, Wageneder proposed adopting the term cerebral electrotherapy (CET) to replace electrosleep in that it more accurately reflected the type of treatment involved (Wageneder & St. Schuy, 1970).

It was after the first International Symposium for Electrosleep and Electroanesthesia in 1966 that North American researchers became interested in CET. Before this symposium, most of the work on CET had been done in the Soviet Union and Europe. Translations of these works revealed sweeping claims for the beneficial effects of CET in a wide variety of disorders in the fields of psychiatry, surgery, dermatology, obstetrics, and pediatrics, but experimental controls were inadequate or nonexistent (Van Poznak, 1969). The American interest in CET research marked the beginning of a somewhat more objective assessment of its effects.

Whereas the Soviet and European researchers had presented a united front in their favorable opinion of the beneficial effects of CET, the American investigators were markedly divided in their opinions, in spite of the fact that the focus of CET research in America had been narrowed down to the main target disorders of anxiety, depression, and insomnia and to certain physiological effects. In general, this division of opinion holds among authors of uncontrolled studies as well as among those who used double-blind procedures in their investigations.

The difficulty in drawing any conclusions is compounded by the considerable differences in the research methods so that comparisons between studies are impossible. This is illustrated by examining in detail eight recent studies that were more rigorous than others because they at least used some kind of double-blind experimental procedure.

Techniques of CET

The technique of administering CET encompasses a bewildering array of different procedures, particularly when the type of electrical stimulation, the duration of the treatment, and the placement of the electrodes are varied.

Electrical Parameters

Either a DC or an AC, in which the current flow regularly changes direction, has been used. Some researchers have added to these a DC bias (Itil, Gannon, Akpinar, & Hsu, 1971; Marshall & Izard, 1974). DC is most frequently used and adheres to the original electrosleep technique and theory in that a constant direction of current is thought to be essential for ensuring unidirectional cerebral cell reactions, an important factor in producing desired physiological modifications (Obrosow, 1959). The pulse frequency, measured in impulses per second or Hz, may vary from 30 Hz to 100 Hz (Rosenthal, 1972a), with a pulse width ranging from 1 to 2 msec (Straus, Elkind, & Bodian, 1964). The supply voltage may vary from 10 to 20 V. The current amplitude at which tingling is usually felt ranges from .1 to .5 mA. These current parameters depend on the type of CET device used, and no two American-made models seem to possess the same electrical characteristics (Brown, 1975). However, the combination of 100 Hz with a pulse duration of 2 msec and an amplitude of up to 1.5 mA are the most frequently used parameters in double-blind studies.

Table 1
Eight Double-Blind Studies and the Technique of Cerebral Electrotherapy

Authors	Current	Frequency (in Hz)	Pulse length (in msec)	Electrode placement	Treatment session No.	Treatment session Duration (in minutes)
Straus, Elkind, & Bodian (1964)	DC	30–40	1.8–2.0	Eyelid +, mastoid −	6–12	30
Rosenthal (1972a)	DC	100	1.0	Mastoid +, orbit −	5	30
Weiss (1973)	DC	45–240	.4–1.2	Brow, nape of neck[a]	24	1–5 2–10 21–15[b]
Feighner, Brown, & Oliver (1973)	DC	100	1.0	Eyelids, mastoids[a]	20	30
Tomsovic & Edwards (1973)	AC	100	2.0	Orbits, mastoids[a]	5	30
Hearst, Cloninger, Crews, & Cadoret (1974)	AC, DC	100	2.0	Mastoids +, brow −	5	30
Marshall & Izard (1974)	DC	100	1.0	Eyelid +, mastoid −	5	30
Moore, Mellor, Standage, & Strong (1975)	DC	100	2.0	Not given	10	30

[a] The polarities of the electrode placements are not given.
[b] The duration of treatment was increased gradually.

Duration of Treatment

Treatment sessions have been known to vary from 30 minutes for 5 consecutive days (Rosenthal, 1972a) to 2 hours daily for a period of several months (Wageneder, Iwanovsky, & Dodge, 1969). It has been reported that exposure to CET for more than 2 hours per session resulted in morning dizziness and a degree of unsteadiness in walking that lasted for a few hours (Iwanovsky & Dodge, 1968). The average duration of exposure time in most of the important studies was 30 minutes per session over an average of 10 sessions.

Electrode Placement

The felt pads attached to the electrodes are either soaked in water (Weiss, 1973) or a saline solution (Feighner, Brown, & Olivier, 1973) or prepared with saline paste (Hearst, Cloninger, Crews, & Cadoret, 1974). A pair of electrodes is placed either directly on the eyelids (Lewis, 1966) or the brow (Brown, 1975). A second pair is usually placed over the mastoids. The forehead electrodes are negatively charged cathodes and those at the mastoids are positively charged anodes (Rosenthal, 1972a), but in some cases their placement is reversed (Marshall & Izard, 1974). There is no firmly established rule about polarity, but the placement of negatively charged electrodes on the forehead and positively charged electrodes over the mastoids is more frequent in the literature (Iwanovsky & Dodge, 1968). However, the direction of current flow appears to be an important factor according to one of the original users of CET, Giljarowskii, who felt that current entering through the orbital fissure and leaving from the mastoid processes was the best method of ensuring electrical penetration of the brain (Boblitt, 1969, p. 12). Since current conventionally flows from the positive to the negative electrodes, the anodes should be anterior relative to the cathodes. A significant reason for such a placement of electrodes is that the only investigation that has demonstrated intracerebral current flow (Dymond, Coger, & Serafetinides, 1975) followed this procedure. The differences in technique between the eight double-blind studies already referred to are set out in Table 1.

Table 2
Eight Cerebral Electrotherapy Double-Blind Studies: Variables in Experimental Design and Outcome

Authors	Target condition	No. of subjects	Cross-over design	Ideal double blind	Tingling sensation during treatment		Experientially identical[a]	Significant difference[a]
					Active	Placebo		
Straus, Elkind, & Bodian (1964)	Insomnia	34	No	No	Yes	Only initially	No	Yes
Rosenthal (1972a)	Anxiety, depression, insomnia	22	No	No	Yes (with loud noise)	No (with loud noise)	No	Yes
Weiss (1973)	Insomnia	10	No	Yes	Yes	Only initially	No	Yes
Feighner, Brown, & Oliver (1973)	Anxiety, depression, insomnia	23	Yes	No	Yes	Only initially	No	Yes
Tomsovic & Edwards (1973)	Tension, head/stomach pain	43	No	No	Yes	Only initially	No	No
Hearst, Cloninger, Crews, & Cadoret (1974)	Anxiety, depression, insomnia	28	No	Yes	Only initially	Only initially	Yes	No
Marshall & Izard (1974)	Depression	40	No	No	Yes	Yes	Yes	No
Moore, Mellor, Standage, & Strong (1975)	Anxiety, depression, insomnia	10	Yes	No	Only initially	Only initially	Yes	No

[a] For comparison of active and placebo treatements.

Setting for Treatment and Method of Administration

It is generally agreed that the best treatment setting is a quiet darkened room in which the patient lies comfortably on a bed. After the electrodes are applied, the current is turned on, and the amplitude is increased slowly to avoid any unpleasant sensation, until the level is reached at which a slight tingling sensation occurs. Some clinicians then reduce the current to a level at which the patient experiences no cutaneous sensation (see Table 2).

Complications and Contraindications

CET is an attractive treatment because it is said to have no cumulative side effects (Weiss, 1973), complications, or contraindications, to be nontoxic and usable with drugs and other therapies, and to be a simple procedure to carry out (Weinberg, 1969). However, side effects such as blurring of vision, thought to be the result of electrode pressure on the eye, and dizziness as well as slight burns on the skin at the electrode sites have been reported (Frankel, 1974; Koegler, Hicks, & Barger, 1971; Rosenthal & Wulfsohn, 1970). Moreover, contraindications such as epilepsy, blood diseases, malignant tumours, cerebrovascular disorders, and heart disease (Chumakova & Kirillova, 1976) as well as various forms of psychosis (Rosenthal, 1972b) have been reported. All of the double-blind studies excluded such patients.

Mode of Action of CET

Before double-blind designs can be discussed, the theories of the mode of action of CET should be considered. These theories must be taken into account when the qualifications of the different placebo conditions are reviewed.

There are two main schools of thought about the action of CET: those researchers who postulate that it has a direct effect on the brain and those researchers who attribute its effect to other causes.

Direct Effect

The effects of CET treatment are attributed to the direct action of the current on the cerebral cells. Rush and Driscoll (1968), in their work on a theoretical model of current flow in the human head, assumed that the current entered the cranium via the frontal surface electrodes. Their calculations suggested that 45% of the electrical output actually entered the brain. Those who favor the direct effect theory hold that the current traversing the brain induces protective inhibition that creates favorable recovery of cerebral cells along with sedation and normalization of the central nervous system (CNS) processes (Banshchikov, 1967; Brand, 1970).

One criticism of the direct effect theory is that the current is too weak to pass from the skin through the skull and other tissues to effect changes in the brain. However, Dymond et al. (1975) provided direct evidence that CET is capable of producing electrical changes in the brain. The proponents of the direct effect theory have mainly been the Soviet and European researchers who were influenced by the original Pavlovian concept of protective inhibition. Kalinowsky (1969) suggested that the therapeutic usefulness of CET lay in the "rhythmic nature of a peripheral stimulation" (p. 172). Iwanovsky and Dodge (1968) described a Soviet work in which the author conclusively stated that CET was a rhythm therapy in which the electrical current provided a kind of "electromassage" that polarized cells and normalized tissue metabolism.

Indirect Effect

The effects of CET treatment are due to the indirect action of the current. The normalization of only the peripheral autonomic elements of the nervous system are involved, and the effect on the CNS is a secondary one involving a variety of mechanisms (Iwanovsky and Dodge, 1968).

The first mechanism is thought to be relaxation, attributable to lying down in a quiet, comfortable, semidark setting. Some reviewers of CET literature have repeatedly stressed the importance of the elements of suggestion inherent in a procedure that calls for patients to lie comfortably in a quiet darkened room and submit to a treamtment that they are told will relax them (Boblitt, 1969; Frankel, 1974; Lewis, 1966).

A second mechanism is sensory stimulation, whereby the rhythmic cutaneous sensations experienced in treatment may alone account for the clinical effects. Such sensory stimuli have been found to induce sleep (Lovell & Morgan, 1942; Oswald, 1960).

A third mechanism is suggestion or a placebo effect, whereby patients who are referred by physicians to undergo a special type of therapy involving neither drugs nor psychotherapy are under the impression that this represents a new type of cure for their specific ailment. The powerful suggestion inherent in electrical apparatus applied to healing has been recognized since the time of Mesmer. The notion that a possible placebo effect played an unimportant role in CET research was promulgated by Giljarowskii, a notion which according to Frankel (1974) probably encouraged many subsequent investigators to adopt a less rigorous approach to their experiment.

Double-Blind Studies

The ideal double-blind procedure is one in which the subject, the operator of the machine, and the individual assessing the effects are all blind. The methodological problems that occur when this is attempted are considerable. Only two of the eight studies listed in Table 2 were able to meet this ideal double-blind or more accurately, triple-blind condition (Hearst et at., 1974; Weiss, 1973).

Treatment Conditions

In three studies the active and placebo CET conditions were identical (Hearst et al., 1974; Marshall & Izard, 1974; Moore, Mellor, Standage, & Strong, 1975). In all of these no statistically significant differences were found between active and placebo treatment (see Table 2). Two types of identical active and placebo CET conditions were devised. One method was to lower the current to just below the point at which tingling was perceived in active treatment. This would be done after subjects had been allowed to experience an initial tingling sensation. Thus an active treatment condition experientially identical to placebo CET, in which the current was turned off completely, was produced.

An alternative method was that of Marshall and Izard (1974), which used positive and negative frontal electrodes and thus enabled the subjects to experience the cutaneous sensation. There was no active treatment because the current was flowing just through the inch of skin separating the electrodes. The electrodes were applied to the mastoid as usual but were not connected to the current. Although all of the studies purported to have kept subjects blind, the first five studies listed in Table 2 did not create active and placebo treatment conditions that were experientially identical to subjects. In some of these studies, subjects felt a tingling sensation throughout active treatment but experienced it only for a brief period at the beginning of placebo treatment. In the placebo treatment the machine would be turned off, persumably without the subjects' knowledge. In other studies, a noise or light used in both treatment conditions was supposed to represent the giving of CET, although the tingling sensation felt in active treatment was absent during placebo treatment. All but one of these five investigations found a significant difference between the active and placebo treatment. The results of these eight studies suggest an association between identical peripheral stimulation and negative outcome and different peripheral stimulation and positive outcome, when active treatment is compared with placebo, although it does not reach statistical significance ($p = .07$, Fisher's exact test). Ensuring experimentially identical active and placebo treatment conditions may be one of the most important factors when the outcome of CET is being assessed.

The implications of these results can be related to the two theories of CET mode of action. Two studies in which subjects felt tingling in neither active nor placebo treatment possibly represented a test of the direct effect theory: The intervening variable of peripheral or rhythmic sensation was not present; therefore, the direct effect alone was being tested. No statistically significant difference between active and placebo treatment was found. In a third study, in which subjects experienced tingling in both active and placebo treatment,

peripheral sensation was held constant. Although both active and placebo treatment groups improved, there was no significant difference between group improvement levels. Thus the indirect effect theory would appear to have been supported once more.

Machine Operator

An additional aspect to ensuring that subjects are blind, given experientially identical active and placebo conditions, is that the operator of the machine also be blind. Frankel (1974) has pointed out the possibility of either indirect verbal or nonverbal communications between the operator and the subject. The application of active or placebo treatment may be identified by the subject from such subtle communications. Such procedures require an intermediary who would only operate the machine while another individual would only interact with subjects. An ideal double-blind procedure is probably best achieved with the use of specially built machines with hidden switches (Frankel, 1974; Weiss, 1973). Perhaps because of the need for extra staff and equipment, only two of the eight double-blind studies were carried out under these conditions (Hearst et al., 1974; Weiss, 1973). In the Weiss study, significant differences between active and placebo CET were found; in the latter study no significant differences were noted.

Assessment of Effects

To prevent the influence of knowledge of type of treatment on assessment, objective psychological measures such as inventories completed by subjects or rating scales completed by a blind clinical assessor should be used. All of the eight double-blind studies under discussion complied with one or both of these conditions.

All these studies used relatively small numbers of subjects. This raises the problem of substantial differences between treatment and control groups before the treatment is administered. To some extent this problem can be obviated by using a crossover design like that employed by Feighner et al. (1973) and Moore et al. (1975). An important aspect to assessment of CET effects, and one that has thus far not been explored in conjunction with psychological and clinical effects, is that of physiological effects. There is a body of research on CET that deals exclusively with physiological effects of CET and does not concern itself with psychological or clinical effects. Probably the most thorough method of properly evaluating the therapeutic effectiveness of CET would be to design a study in which CET's effect on a target disorder is assessed with objective psychological, physiological, and clinical measures and in which subjects serve as their own controls in a crossover design. Such a study has been completed by the authors and will be published in the near future.

Conclusion

It is clear that the confusion about the actual therapeutic value of CET stems in part from the diversity of methodological approaches and from the varying degrees of scientific rigor that have been used in CET research.

Any further research on CET would be of little value unless the scientifically sound components of all these studies are combined to produce a design that allows no room for bias.

Suggestions for Future Investigations of CET

Based on this discussion of the various techniques and methodologies of CET research, the designers of future studies should consider the following points:

1. Electrical parameters have been limited to a pulse frequency of 100 Hz and a duration of 2 msec. Little consideration has so far been given to the effects of varying the pulse frequency and duration.
2. Treatment duration—The effects of the duration and frequency of treatments have not been systematically studied.
3. Electrode placement and polarity.
4. Treatment conditions—Ideally, the subjects, the operator of the machine, and the clinical assessors should be blind. Subjects' phenomenological experience of treatment

should be identical under all experimental conditions.

5. Assessment—Objective psychological and physiological measures should be used, along with blind assessment of the changes in the subjects' clinical condition.

Temporal Versus Spatial Information Processing Theories of Hippocampal Function

Paul R. Solomon
Williams College

A series of articles by Black, Nadel, O'Keefe, and their co-workers propose that the primary function of the hippocampus is to process spatial information. Although the spatial information processing view of hippocampal function accounts for much of the available data, it cannot account for the data from the classically conditioned rabbit nictitating membrane response preparation. The present article reviews these data and suggests that the hippocampus is involved in the processing of temporal as well as spatial information.

A number of recent studies by Black, Nadel, O'Keefe, and their co-workers propose that the primary role of the hippocampus is to process spatial information (see Nadel & O'Keefe, 1974; Nadel, O'Keefe, & Black, 1975, for reviews). According to this theory, the hippocampus acts as part of a neural system that forms a cognitive map of the environment. Central representations of separate places in the environment as well as the relationship of one place to any other place are represented in this system. Thus once an animal has located itself in the environment by using the available cues, it can use its spatial mapping system to locate other places.

Central to the spatial hypothesis of hippocampal function is that the role of the hippocampus is to process spatial but not temporal information. As O'Keefe and Black (1979) point out, cues are only critical to the extent that they allow the animal to identify a starting point (e.g., the start box in a maze). Once this point has been identified, the animal can find any place in the environment by using the mapping system. Furthermore, once the starting point is perceived, the animal's spatial map is not sensitive with respect to its own body position or orientation, nor is the map sensitive to cues in the environment (O'Keefe, 1976).

To support the spatial information processing view of hippocampal function, its proponents have presented data from both electrophysiological (O'Keefe, 1976; O'Keefe & Black, 1979; O'Keefe & Dostrovsky, 1971; Olton, Branch, & Best, 1978) and lesion (Black, Nadel, & O'Keefe, 1977; O'Keefe & Black, 1979; O'Keefe, Nadel, Kieghtly, & Kill, 1975; Olton, Walker, & Gage, 1978) studies. The data and logic from both these lines of research strongly implicate the hippocampus in spatial mapping. The authors, however, overlook an accumulating body of literature on the role of the hippocampus in aversive classical conditioning of the rabbit's nictitating membrane response (NMR). In this article I argue that place learning plays little if any role in classical conditioning of the rabbit's NMR and if this is the case, the data pertaining to hippocampal function in this preparation cannot be explained by the spatial information processing hypothesis.

The Spatial Information-Processing Hypothesis and Classical Conditioning

The proponents of the spatial information-processing view of hippocampal function do not

Some of the research described in this proposal was supported by National Science Foundation Grant BNS-77-14871 and a faculty research grant.

I would like to thank Andrew Crider, John W. Moore, W. Ronald Salafia, and Richard F. Thompson for their helpful comments on an earlier version of this article.

directly address the question of what changes in aversively motivated classically conditioned behaviors might be expected in animals with hippocampal lesions. They do, however, point out that place learning does not involve learning about the temporal relationships between stimuli:

> When an animal is learning about the spatial relationships among stimuli, we assume that it employs place strategies. When it is learning about the temporal relationship between stimuli we assume that it employs cue strategies. (Black et al., 1977, p. 1108.)

The authors assume that place learning involves the acquisition of knowledge of the spatial relationships between two stimuli and that this knowledge is acquired independently of (and via different neural substrates than) knowledge of temporal relationships (cue learning). The hippocampus, in their view, is critical for learning the spatial aspects of a relationship between stimuli but unimportant for learning the cuing of temporal relationships. Black et al. (1977) make this explicit in reviewing the data that indicate no deficit in taste aversion learning in animals with hippocampal lesions: "This result is to be expected, since this procedure (taste aversion) does not seem to involve spatial strategies, at least as it has been employed so far" (p. 1123).

The strong implication here is that hippocampal lesions should not affect the temporal associations made in a classical conditioning preparation such as the rabbit NMR. As I point out in subsequent sections, although there are some tasks in which hippocampal lesions do not seem to affect the classically conditioned NMR, there are others in which animals with hippocampal lesions differ from controls. Furthermore, the electrophysiological data and the data from brain stimulation studies also implicate the hippocampus in classical conditioning of the NMR.

Absence of Spatial Cues in the Rabbit NMR Preparation

Black et al. (1977, p. 1108) state that when an animal is learning spatial relationships between stimuli, it is using place strategies, and when it is learning temporal relationships between stimuli, it is using cue strategies. The authors also point out that, although an animal performs successfully in a particular situation, it may be difficult to determine to what degree each strategy is being used. Consequently, it may be necessary to make a priori assumptions about each task.

Although it is possible that spatial learning is involved in classical conditioning paradigms such as the conditioned emotional response (CER) (see Black et al., 1977, p. 1114), it is unlikely that spatial cues play any role in the rabbit NMR preparation. Here, the animal remains virtually motionless throughout the conditioning session, and the conditioned stimuli (CS) and unconditioned stimuli (UCS) are delivered in the same spatial locations at all times. Thus any associations, for example, between the CS and the UCS, would necessarily be temporal in nature.

The rabbit NMR preparation used in most laboratories is a variation of that described by Gormezano (1966). The rabbit is restrained in a Plexiglas box with an adjustable plate and ear clamp securing the head and a second plate placed over the animal's back to restrict body movement. Some experimenters further restrain the animal's head by implanting long bolts in the animal's skull and fastening them to the plexiglas box (e.g., Frey, Maisiak, & Dugue, 1976; Mis, 1977). Animals are typically run in individual sound-attenuated and darkened chambers. A panel in front of each chamber contains two lights that serve as visual CSs and speakers for delivering auditory CSs. Several laboratories (see Wagner, Rudy, & Whitlow, 1973) also use a vibratory CS delivered to the back of the animal.

The UCS is typically a 1–3 mA infraorbital shock, although some experimenters prefer an air puff. The unconditioned response (UCR) and conditioned response (CR) are lateral movements of the nictitating membrane. This response is recorded by attaching the shaft of a potentiometer to the NM, thus transducing the response into a DC signal. A typical session in our laboratory consists of 100 CS–UCS pairings in a 50-minute session.

Lesion Studies

Since acquisition of the rabbit's NMR is not dependent on spatial strategies, the spatial information processing theory would predict

that hippocampal lesions should have no effect on this behavior. This, in fact, seems to be the case. Several studies (Schmaltz & Theios, 1972; Solomon, 1977; Solomon & Moore, 1975) reported no differences in acquisition of the NMR in animals with bilateral aspiration lesions of the dorsal hippocampus, animals with lesions of the overlying cortex, or unoperated controls. The dependent measure in these studies was either total CRs or trials to criterion. This, however, does not rule out the possibility that other more subtle aspects of the nacent CR, such as amplitude, latency, or interstimulus interval (ISI) shifts, could have been affected.[1] In addition, there are electrophysiological data (see the Electrophysiological Studies section) which suggest that the intact hippocampus is involved in acquisition of the CR.

Although the acquisition data may be consistent with the spatial processing view of hippocampal function, there are data from other tasks conducted in the rabbit NMR preparation that are not. Like simple acquisition, these tasks require that the animal learn a temporal relationship between a CS (or a series of CSs) and a UCS (or the absence of a UCS). Unlike acquisition, these tasks require that the animal learn not to respond in certain circumstances. In these situations the animal must learn whether a particular CS is relevant, that is, if it uniquely predicts the occurrence or nonoccurrence of the UCS. These tasks require the animal to learn temporal relationships between CSs and UCSs and thus, according to spatial information processing theory, should be performed equally well by animals with and without the hippocampus.

Latent inhibition (LI) is one behavior that is disrupted in animals with hippocampal lesions. In this paradigm the animal is preexposed to the to-be-conditioned CS, and this preexposure results in retarded acquisition of the CR when the CS is subsequently paired with the UCS in a conditioning paradigm. In one study conducted on the LI effect (Solomon & Moore, 1975), we reported that whereas 450 tone preexposures resulted in a decrement in conditioning for normal rabbits and for rabbits with cortical ablations, animals with dorsal hippocampal ablations showed no such decrement; that is, they conditioned as fast as nonpreexposed controls. Our interpretation of these data was that the hippocampus is part of a system involved in learning to ignore irrelevant stimuli. To further test this view of the role of the hippocampus, we investigated the effects of dorsal hippocampal ablations in Kamin's (1968, 1969) two-stage blocking paradigm.

The typical blocking paradigm in the rabbit NMR preparation consists of a two-group design (cf. Marchant & Moore, 1973). In Stage 1 the blocking group is presented with a tone that is paired with an eyeshock UCS until the CR is well established. Animals in the control condition are yoked to the blocking animals and simply sit for a corresponding amount of time with no CS or UCS presentations. In Stage 2 both groups are conditioned to a compound CS that consists of the tone from Stage 1 plus a light. After both groups display a high level of conditioning to the compound, the test phase is introduced. During testing, all animals are presented with nonreinforced presentations of the tone interspersed with nonreinforced light presentations. In general, whereas animals in the control condition give CRs to both the tone and light, animals in the blocking groups respond only to the tone (Marchant & Moore, 1973).

Although Kamin (1968) initially suggested that prior conditioning to the tone caused the animal not to notice the light when it was presented in compound with the tone, more recent evidence (Kamin, 1969; Mackintosh, 1973, 1975) suggests that the animal does initially attend to the redundant CS but does not condition to it, since the light provides no new information regarding the reinforcing event. Thus the paradigm is similar to LI in that the animal must learn to ignore an irrelevant stimulus. If a tuning-out process similar to the one in latent inhibition is operating here, hippocampal lesions should disrupt the blocking effect. Solomon (1977) reported just this finding. Although normal rabbits and rabbits with cortical lesions showed the typical blocking effect, hippocampectomized rabbits did not. Animals with dorsal hippocampal ablations re-

---

[1] I am grateful to Michael M. Patterson (Note 1) of Ohio University for suggesting this as yet untested possibility.

sponded to both the tone and light during testing.

Conditioned inhibition (CI) is yet another behavior in which an animal must learn not to respond in certain situations. Both we (Solomon, 1977; Moore, Mis, & Solomon, Note 2) and Black et al. (1977; Nadel et al., 1975) agree that the hippocampus is not critical to inhibitory processes. But whereas Black et al. argue against the inhibitory hypothesis of hippocampal function in favor of a spatial hypothesis, we maintain that CI, unlike blocking and LI, does not involve learning to ignore an irrelevant stimulus and thus should not be affected by hippocampal damage.

Although a number of theoretical accounts of hippocampal function have stated that the hippocampus plays a direct role in Pavlovian conditioned (e.g., Kimble, 1968) or internal (e.g., Douglas, 1967) inhibition, only recently has this been directly tested. In the Pavlovian CI paradigm, the animal is taught to discriminate between CS_A, which is always followed by the UCS, and a compound consisting of $CS_A + CS_B$, which is never followed by the UCS. Since CS_B is negatively correlated with the UCS, it should become inhibitory (Hearst, 1972; Rescorla, 1969). That is, when CS_B is presented alone and reinforced, acquisition of the CR should be retarded relative to controls. Experimenters using the rabbit NMR preparation have indicated that this is the case in normal rabbits (Marchant, Mis, & Moore, 1972; Marchant & Moore, 1974; Mis, 1977), and Solomon (1977) showed that this was also true for rabbits with dorsal hippocampal ablations.

Black et al. (1977) would likely argue that the failure to find a disruption of CI indicates that no spatial cues were involved. This appears to be true; however, this is not the factor that separates this paradigm from blocking and LI. Rather, we propose that the difference between CI, in which hippocampal lesions have no effect, and blocking and LI, in which they do, is that CI does not involve the tuning out of an irrelevant stimulus. In the Pavlovian CI paradigm, despite the fact that CS_B is not followed by the UCS, CS_B cannot be ignored. If the animal attempts to tune out CS_B, it could not make the distinction between CS_A and CS_{A+B}. Thus the failure to find a disruption of CI, at least from our theoretical perspective, was not surprising.

In summary, the data on the role of the hippocampus in acquisition of the classically conditioned NMR may be consistent with the spatial hypothesis of hippocampal function (but see the next section). Hippocampal lesions do, however, disrupt blocking and LI of the rabbit's NMR, but they do not seem to affect CI in this paradigm. Since each of these tasks involves temporal relationships between stimuli, it is not likely that a spatial hypothesis of hippocampal function can account for the differences. Rather, it appears that these data are best explained in terms of the role of the hippocampus in learning to ignore irrelevant stimuli.

Electrophysiological Studies

As I indicated earlier, much of the support for the spatial mapping hypothesis stems from electrophysiological data (O'Keefe & Black, 1979; O'Keefe, 1976; O'Keefe & Dostrovsky, 1971; Olton et al., 1978). These studies indicated that single-unit activity in the hippocampus was related to place but not to cue learning. There is, however, substantial electrophysiological data from the rabbit that implicates the hippocampus in classical conditioning of the rabbit's NMR. This work has been carried out by Thompson and his coworkers (Berger, Alger, & Thompson, 1976; Berger & Thompson, 1978a, 1978b; Berry & Thompson, 1978; Thompson, 1976).

Berger et al. (1976) reported increased neural activity in the hippocampus during pairings of a tone CS and corneal air-puff UCS. They found an increase in neural activity in both the pyramidal and granule cell layers of dorsal hippocampus that correlated with the behavioral CR. This increased neural activity, which the authors suggest may be one of the earliest neuronal indicators that learning has occurred, begins early in conditioning (in fact, during the first eight, CS–UCS pairings) and precedes the behavioral response by 35–40 msec. Initially, the neuronal response precedes the UCR, but as CRs begin to occur, the neuronal activity both increases and moves forward in the CS–UCS interval and always precedes the behavioral response by 35–40

msec. Furthermore, there was no increase in activity in unpaired controls, ruling out the possibility that the activity was due to pseudoconditioning, sensory registration, or motor output. A subsequent study (Berger & Thompson, 1978a) investigated single-unit activity in hippocampal pyramidal cells. As in the case of multiunit activity, the behavior of these cells was well correlated with the conditioned NMR.

Additional evidence for the role of the hippocampus in classical conditioning of the rabbit's NMR comes from a recent study by Berry and Thompson (1978). In this experiment, the authors were able to predict the rate of acquisition of the NMR by examining the hippocampal electroencephalogram (EEG) prior to conditioning. They found that animals that displayed relatively high levels of activity in the high-frequency category (8–22 Hz) conditioned more slowly than animals that showed a higher proportion of activity in the low-frequency range (2–8 Hz). Berry and Thompson suggested that this may be an indication that "behavioral state," as indicated by the hippocampal EEG, is an important factor in learning. Interestingly, Moore, Goodell, and Solomon (1976) reported that the cholinergic blocker scopolamine, which disrupts hippocampal activity in the low-frequency range (see Stumpf, 1965), greatly retards conditioning of the NMR to a tone or a light CS.

At first glance, the electrophysiological data on acquisition of the NMR may seem inconsistent with the results of lesion studies: If a structure is involved in a behavior, should not removal of the structure affect that behavior? Not necessarily. The finding that removal of a structure does not disrupt conditioning should not be interpreted to mean that the structure does not participate in the behavior in the intact animal. Furthermore, as Thompson (1976) pointed out in regard to the electrophysiological data, there is the possibility that brain structures besides the hippocampus (e.g., brainstem) may show similar changes in activity early in conditioning. Thus it may be that the hippocampus is monitoring the activity of other areas. If this is the case, hippocampal lesions would not necessarily disrupt acquisition of the CR. Finally, as mentioned earlier, the effects of hippocampal lesions have only been investigated in terms of crude dependent measures such as the presence or absence of a CR. A more fine-grained analysis of the effects of hippocampal ablation on conditioning of the NMR may yield differences.

Electrical Stimulation of the Brain

Like the data from lesion and electrophysiological studies, research using electrical stimulation of the brain also implicates the hippocampus in conditioning of the rabbit's NMR.

A recent study by Salafia, Romano, Tynan, and Host (1977) found that posttrial stimulation of the hippocampus immediately following the UCS offset retarded conditioning of the NMR. Once CRs began to occur, however, posttrial stimulation was without effect. The level of electrical stimulation in these studies did not produce convulsions, but it was sufficient to evoke poststimulation seizure activity in hippocampus. Based on these data, Salafia et al. (1977) concluded that the disruptive effects of posttrial hippocampal stimulation primarily affected association processes, as opposed to either the registration of the stimulus or the execution of the response. Subsequent work by Salafia (Salafia, Chiaia, & Ramirez, in press) indicates that the development of the CR can be as severely retarded if subseizure stimulation is used in either the dorsal hippocampus or amygdala.

Spatial and Temporal Information Processing in the Hippocampus?

Black et al. (1977) propose that the hippocampus is involved in the formation of spatial maps of the environment. The data and arguments presented by these authors as well as the data presented by researchers working in similar paradigms (e.g., Olton et al., 1978) suggest that this is indeed *one* function of the hippocampus. Nevertheless, the evidence from the rabbit NMR preparation indicates that at least in the rabbit, the hippocampus is involved in other processes.

Since most of the data that support the spatial information processing theory are based on the rat, it is tempting to speculate that the apparent discrepancies between these argu-

ments and those presented in this article are entirely due to species differences. Although differences in species and perhaps more importantly, differences in how dependent each species is on spatial information, are likely to account for some of the variability, it is equally likely that these differences do not account for the entire discrepancy. For example, Black et al. (1977, p. 1113) cite many studies that show facilitated avoidance learning in hippocampectomized animals. To explain this facilitation, they argue that these animals are not subject to interference from spatial cues. This facilitated avoidance, however, occurs not only in rats but also in hippocampectomized rabbits (Papsdorf & Woodruff, 1970). Similarly, we (Solomon & Moore, 1975) claimed, on the basis of rabbit NMR data, that the disruption of LI and blocking in animals with hippocampal lesions was due to the animal's inability to learn to ignore an irrelevant stimulus. These findings are not unique to the rabbit, as similar results have been reported for the rat in LI, using both the two-way avoidance (Ackil, Melgren, Halgren, & Frommer, 1969) and taste aversion paradigms (McFarland, Kostas, & Drew, 1978) and in blocking in the CER paradigm (Rickert, Bennett, Lane, & French, 1978). Furthermore, Patterson, Berger, and Thompson (1979) found that hippocampal-unit activity in the cat during NMR conditioning is similar to that found in the rabbit. This suggests that the electrophysiological evidence in the rabbit NMR preparation is also not species dependent. Thus, although it is possible that the rat is more of a spatial animal than the rabbit, especially the restrained rabbit, this potential difference cannot explain the apparent discrepancies in hippocampal function between the two species. (But see Winson, 1972, for a discussion of species differences and hippocampal function.) Rather, it seems that although the hippocampus may be involved in spatial information processing, it may be implicated as well in the processing of temporal information about stimuli.

Without attempting to add yet another all-encompassing theory of hippocampal function, I would like to suggest that in addition to the formation of spatial maps (and no doubt participation in a variety of other functions; see Isaacson & Pribram, 1975, pp. 429–442; Nadel & O'Keefe, 1974, for a review of the reviews) *one* function that the hippocampus might participate in is a type of "temporal mapping."[2] By this I simply mean registration of the temporal sequence of events. In the rabbit NMR preparation, this would be a coding of the relationship between the CS or the CSs and the UCS. Thus in LI the hippocampus receives information that a CS has occurred and that it is not followed by a relevant (i.e., motivationally significant) event, namely, the UCS. Consequently, the hippocampus participates in a process whereby the irrelevant stimulus is tuned out. One interesting way to test this idea of hippocampal function in LI would be to record from the hippocampus not only during stimulus preexposure but perhaps more importantly, during conditioning following the stimulus preexposure. Although this has yet to be done in the rabbit, Best and Best (1976) presented data from an LI paradigm in the rat that showed increased firing in hippocampal cells during conditioning for nonpreexposed animals but decreased activity in animals that had been preexposed.

In blocking, the animal learns a slightly more complex temporal sequence: CS_A always predicts the UCS, and any additional information (e.g., CS_B) in regard to the UCS is redundant and, like a preexposed stimulus, should be tuned out.

The notion of temporal information processing may also be consistent with the data on excitatory conditioning despite the finding that hippocampal lesions do not disrupt this form of learning. In excitatory conditioning the hippocampus may receive information that a CS has occurred and that it is closely followed by a relevant event, the UCS. This temporal sequence is coded in the hippocampus and this coding may account for the change in neural activity reported by Thompson and his coworkers during CS–UCS pairings. In fact, Thompson notes (cf. Berger & Thompson, 1978b) that hippocampal-unit activity actually

[2] I am grateful to John W. Moore of the University of Massachusetts at Amherst for discussions on temporal information processing in the hippocampus. See Moore (1979), who proposes a neural model to account for many of the phenomena discussed in this article.

forms a temporal model of the temporal form of the behavioral NMR. Since the CS is paired with a relevant event, the UCS, the hippocampus should not act to tune it out. Furthermore, although a hippocampectomized animal loses the ability to tune out irrelevant stimuli, this would have no effect on simple acquisition, since tuning out an irrelevant stimulus is not required. Thus, whereas the hippocampus receives information about the sequence of events transpiring during excitatory conditioning, it need not initiate action, since the CS is relevant. Consequently, hippocampal lesions have no effect on acquisition of the CR. This is not to say that the hippocampus is not critical to acquisition of the CR under certain circumstances. For example, animals with hippocampal lesions should be more susceptible to the deleterious effects of external inhibitors (distractors) on conditioning, and there is some preliminary data to suggest that this is the case (Solomon & Moore, 1975, Experiment 2).

Salafia et al.'s (1977) posttrial stimulation data also fit nicely into this scheme. Hippocampal stimulation could result in the tuning out of all stimuli, both relevant and irrelevant, and would thus have the effect of retarding conditioning.

In summary, it may be that the hippocampus is capable of establishing the relationship (or to use Black et al.'s terminology, "maps" the relationship) between many kinds of stimuli. Certainly the seemingly redundant lamellar organization of the structure (e.g., Anderson, Bliss, & Skrede, 1971) coupled with its anatomical relationships to sensory and "motivational" systems of the brain suggests this potential. What type of mapping occurs, however, may depend on what animal is being investigated, what type of stimuli are available, and what type of problem the animal is asked to solve.

Tuning Out Irrelevancy? Comments on Solomon's Temporal Mapping View of the Hippocampus

John O'Keefe
Department of Anatomy
University College London, London, England

Lynn Nadel and Jeff Willner
Dalhousie University, Nova Scotia, Canada

In his article, Solomon proposes an extension to the cognitive map theory of hippocampal function. He cites evidence drawn mainly from the literature on the classical conditioning of the rabbit's nictitating membrane response (NMR), which he claims can not be satisfactorily explained within the framework of the present theory. Although rabbits with hippocampal lesions acquire the conditioned response as rapidly as do normals and show normal conditioned inhibition, they do not show latent inhibition or blocking. Single-unit and multiple-unit recordings during NMR conditioning show that some hippocampal cells begin to increase their firing rates during the conditioned stimulus period as learning takes place. Posttrial electrical stimulation of the hippocampus retards NMR conditioning. To explain these findings, Solomon proposes that in addition to its spatial mapping function, the hippocampus might also function as a temporal map. A temporal map would register the temporal relationship between stimuli and "tune out" irrelevant stimuli. In this article we examine the studies that Solomon cites as incompatible with the spatial map theory. We show that the deficits following hippocampal lesions can be predicted from an understanding of the role of place learning in each paradigm, and we show that the electrophysiological data are open to different interpretation. We conclude that the data cited by Solomon do not require any modification of the theory.

In his article, Solomon (1979) comments on our spatial map theory of hippocampal function and points to what he sees as its inadequacies in dealing with a certain set of data. Although he allows that "the spatial information processing view of hippocampal function accounts for much of the available data" (p. 1272), he argues that "it cannot account for the data from the classically conditioned rabbit nictitating membrane response preparation" (p. 1272). After reviewing data from both lesion and electrophysiological experiments on the rabbit's nictitating membrane response (NMR), he concludes that our theory needs to be modified: In addition to its spatial mapping function, the hippocampus must also participate in a type of temporal mapping. During NMR conditioning, a temporal map would encode the temporal relationship between the conditioned stimulus (CS) or CSs and unconditioned stimulus (US) and participate in a process whereby irrelevant stimuli (ones not signaling changes in reinforcement contingencies) are ignored or "tuned out." He thus seeks to broaden the information content of the map and at the same time re-

strict its output function to the inhibitory one of filtering out sensory stimuli.[1]

Although we are not against modification and extension of the theory in principle (see, for example, our discussion of semantic maps in O'Keefe & Nadel, 1978), we feel compelled to resist Solomon's particular modification. The reasons for doing so are set out in an earlier article on the distinction between theories and hypotheses (Nadel & O'Keefe, 1974). In brief, the power of the theory as it now stands derives from its ability to make clear predictions that can be tested and judged to be correct or incorrect. Solomon's modification would overextend the theory's explanatory power at the expense of its predictive power. Let Solomon say it: "In summary, it may be that the hippocampus is capable of establishing the relationship (or to use Black et al.'s terminology, "maps" the relationship) between many kinds of stimuli . . . . What type of mapping occurs, however, may depend on what animal is being investigated, what type of stimuli are available, and what type of problem the animal is asked to solve" (pp. 1278). In short, the new hybrid theory has been reduced to an hypothesis, all of the important questions to be answered by ad hoc postulates. Before allowing that to happen, we must examine carefully Solomon's assertions and the data on which they rest. We try to show that these data are only apparently in conflict with the cognitive map predictions. His article is divided into four parts and we follow that order in our comments. In the first part (the section on The Spatial Information Processing Hypothesis and Classical Conditioning and the section on Absence of Spatial Cues in the Rabbit NMR Preparation), Solomon discusses our spatial map theory and concludes that there is little or no role for the mapping system in classical conditioning of the rabbit NMR. We are at pains to deny this and point to several ways in which the map could be involved and how these ideas can be tested. In the second part of his article (the section on Lesion Studies), Solomon reviews experiments on the effects of hippocampal lesions on classical conditioning, especially that of the NMR. He concludes that lesions do not affect the acquisition of simple excitatory conditioning or the development of conditioned inhibition but that they do disrupt latent inhibition and blocking. Here we look more closely at the role of background cues (i.e., places) in these paradigms and conclude that the data do not support Solomon's interpretations. In his third part (the sections on Electrophysiological Studies and Electrical Stimulation of the Brain), Solomon cites recent experiments that show changes in multiple-unit and single-unit recordings from the hippocampus during classical conditioning of the NMR. We have commented briefly on these studies elsewhere (O'Keefe & Nadel, 1978, pp. 190–194) and extend those comments here. In a final part (the section on Spatial and Temporal Information Processing in the Hippocamus), Solomon gives a resume of his own notion of a temporal map. We feel that the notion as presented has little explanatory power and constitutes an unjustified and unnecessary extension of the hippocampal cognitive map theory.

Place Cues: Their Role in Classical Conditioning

Solomon asserts that place learning plays little if any role in classical conditioning of the rabbit NMR because "the animal remains virtually motionless throughout the conditioning session, and the conditioned stimuli (CS) and the unconditioned stimuli (UCS) are delivered in the same spatial location at all times" (p. 1273). Solomon may be forgiven for misunderstanding our position, since we have not emphasized the role of place learning in classical conditioning, but we are somewhat surprised that he has chosen to ignore the recent experimental and theoretical literature that points to the importance of background cure or places in classical conditioning.[2]

---

[1] It is not clear whether Solomon intends the restriction of the output function to be applied only to the enlarged map's temporal functions or to the spatial functions as well. We have presented the arguments against a general inhibitory function for the hippocampus elsewhere (e.g., Nadel & O'Keefe, 1974; Nadel, O'Keefe, & Black, 1975) and will not repeat them here.

[2] One gets the impression that the term "background cues" is used to refer to a collection of individual cues that, although unidentified, do not differ in principle from the specific foreground CSs. We have argued that this view is only partially correct: In most experimental situations the major role of the background

According to the cognitive map theory, there are three different ways that the hippocampus can be involved in learning and performance.

1. Learning about places: Organisms built maps of environments. An environment or specific places within it can be tagged as dangerous or as containing rewards such as food or water.

2. Strategies using places: Using its map, the animal can identify its position within the environment as well as the distance and direction to other places.

3. Attention to places: The mapping system can aid in learning about a stimulus in an environment either by directing the animal's attention to particular places in which that stimulus occurs or by assessing the stimulus as novel, that is, one that is not represented in the mapping system as occurring in that place in the environment.

One way in which Pavlovian tasks differ from instrumental tasks is that they rule out the second use of the mapping system as a successful strategy for solving problems; by definition, nothing the animal does can affect the contingency between the CS and US. This does not mean that the animal won't try to use such place strategies; under certain circumstances they may actually conflict with what the experimenter is measuring as learning.

Several experiments have pointed to the role of place factors in Pavlovian conditioning. Sheffield (1965) reported that during classical conditioning of the salivary response, dogs would often emit bursts of salivation during the intertrial interval:

> These bursts are such an ever-present nuisance that the experimenter, who is watching the dog, the polygraph, and the tape that programs trials, is kept in a continual state of anxiety lest a burst start just ahead of CS, spoiling the record of what otherwise might be a clear cut CR. Also it is often difficult to tell whether a "CR" was actually a response to the CS or whether it was a lucky burst, accidentally timed with the CS. Moreover, the bursts between trials look so much like the response to CS that one is obliged to raise the question of whether the bursts also have a "CS" and if so, what the nature of this unobserved CS is. (p. 314)

These bursts were maximal early in conditioning, declining somewhat later in training. Sheafor (1975) has studied such pseudoconditioned responses during classical conditioning of the rabbit's jaw movement using a water US. He concluded that they resulted from an association of the background cues with the US and were not due to trace or temporal conditioning to the specific foreground CS. Part of his evidence was that these pseudoconditioned CRs could be extinguished by leaving the animal in the test situation without presentation of the CS or US.

The most straightforward way to test for the development of a place hypothesis during classical conditioning is to carry out probe trials during which the animal is tested in a different environment or is freed from restraint and put either in the usual testing place or in a new nearby place. Zener (1937) was the first to do these latter tests and some of his results might be interpreted as support for place learning. When put unrestrained on a new testing stand and presented with a CS signaling food, the dog left the new stand, went over to the usual stand and waited for the food to be delivered. There is some indication that the animal would have moved from the new table to the old in the absence of the CS but was prevented from doing so by Zener. In response to a different CS that signaled acid in the mouth, the same animal first left the new platform and returned to the usual testing place but then turned around and walked away from it.

In certain classical conditioning paradigms, this kind of place learning seems to conflict with conditioning to the experimenter-designated CS. Rescorla and Wagner (1972) have suggested that a particular US has a limited amount of associative strength and that this must be shared amongst all of the stimuli conditioned to it. The amount of conditioning to each stimulus depends on how good it is at predicting the US in relation to other stimuli in the situation. In the standard classical conditioning paradigm, this associative strength is, at least initially, shared between the background and a compound consisting of the

---

cues is to identify environments or specific parts of an environment. These *places* have some properties in common with foreground CSs but differ in many important respects (see O'Keefe & Nadel, 1978, pp. 80–101). Here we assume that most of the effects attributed to background cues are due to their role in defining places.

background cues and the specific foreground CS. Manipulations that alter the strength of conditioning to the background cues should have an inverse effect on conditioning to the specific foreground CS and vice versa. Whether one accepts the notion that there is a limited amount of associative strength to be shared (see Mackintosh, 1975, for an alternative view), it seems clear that spatial context can influence conditioning to specific foreground CSs. Several experiments provide support for this idea.

In a conditioned emotional response (CER) study, Dweck and Wagner (1970) showed that extinguishing the fear associated with the background cues by exposing the animal to the environment in the absence of the CS and US during training increased conditioned suppression to the specific CS. Odling-Smee (1978) confirmed this finding in a somewhat different situation, whereas Odling-Smee (1975) showed the converse: Increasing the correlation between the specific CS and US reduced the aversiveness of the place in which conditioning occurred, even though establishing a perfect correlation between CS and US did not totally eliminate fear of the training environment. Taken together, these studies support the notion that fear can be conditioned to the environment and suggest that the degree of such conditioning is influenced by the reliability with which the specific stimuli and the spatial context (i.e., background cues) predict the US.

In addition to participating in conditioning in the manner previously described, the mapping system also can become involved through its misplace subsystem. This component detects discrepancies between the stored representations of the spatial array of stimuli that occur at a particular place in an environment and those that the animal perceives at any given moment. Mismatches generate exploration that serves to incorporate the changes into the new representation of that place. We have argued that the introduction of a new stimulus into an environment has two kinds of effects: One effect is due to its novelty, which generates a mismatch in the hippocampus, and the other is due to its noticeability, which depends on the properties of the sensory analyzers, how intense the stimulus is, how recently it or a similar stimulus has been experienced, and so forth.

Unlike noticeability, the novelty of a stimulus depends on the environmental context in which it occurs. This being the case, the mapping system should be involved in those aspects of Pavlovian conditioning for which novelty is a critical factor. In latent inhibition (LI), for instance, experience with a stimulus and hence a reduction in its novelty retards its subsequent associability with a US (e.g., Lubow, 1973). This loss of associability seems limited to the context in which exposure to the stimulus occurred. Lubow, Rifkin, and Alek (1976) looked at the effect of exposure to olfactory stimuli in the same or different environments. LI was only obtained when the CS was preexposed in the same environment in which conditioning subsequently occurred. There was no retardation of conditioning to a CS that had been preexposed in a different environment. These data suggest that the hippocampal mapping system is involved in LI: By defining the context of occurrence, the map makes novelty possible.

In sum, the hippocampal cognitive map theory predicts that the hippocampus is involved in classical conditioning, often in rather subtle ways. We can now turn to the changes that Solomon cites as inexplicable within the framework of the theory as it stands.

No Change in NMR Acquisition After Hippocampal Lesions

Solomon concentrates on the effects of lesions on various conditioning paradigms involving the rabbit NMR but also makes reference to other conditioning studies. He admits that hippocampal lesions do not affect acquisition of the NMR, which is in line with the mapping theory, but suggests that more sensitive response measures might reveal subtle changes in amplitudes, latency, or interstimulus interval (ISI) shifts. In view of Sheafor's (1975) evidence that CRs can be elicited and influenced by background cues, we concur. It is not immediately apparent, however, how Solomon's ideas would explain such effects.

Hippocampal Lesions, LI, and Blocking

We now turn to a closer examination of the conditioning paradigms in which hippocampal lesions do produce deficits and to the interpretation Solomon places on these data. We begin with an analysis of LI, briefly discuss blocking, and then move on to conditioned inhibition, which provides a critical test of our respective positions. Our argument throughout will be that (a) place learning does have a role in certain Pavlovian procedures, and (b) the effects of a hippocampal lesion on an animal's performance in any given paradigm can be predicted from a knowledge of the role of place learning in that procedure.

Solomon and Moore (1975) have shown that LI in NMR conditioning is disrupted by hippocampal lesions. Solomon (1979) cites two other studies that have found a failure of LI in different paradigms as evidence of the generality of the effect (Ackil, Mellgren, Halgren, & Frommer, 1969, in two-way avoidance, and McFarland, Kostas, & Drew, 1978, in taste aversion learning[3]).

Our theory already predicts an effect of hippocampal lesions on LI insofar as it is dependent on environmental context; there is no need to extend the theory in the way suggested by Solomon. Moreover, taken as it stands, the cognitive map theory suggests a more comprehensive interpretation of this phenomenon. One LI study that Solomon failed to cite was reported by Olton and Isaacson (1968). Superficially similar to the Ackil et al. study cited by Solomon in that it used a two-way avoidance task, this study found that preexposure to the CS facilitated rather than retarded subsequent learning in intact rats. In neither study did preexposure influence learning in the lesioned rats. The failure to obtain preexposure effects in the lesioned animals is explicable; the opposed effects of CS preexposure in the intact rats in these two studies is less so.

Analysis of the two-way task in terms of the role of place and other kinds of learning helps to clarify this apparent discrepancy. The normal intact animal has considerable difficulty in learning two-way avoidance. In Black, Nadel, and O'Keefe (1977) we argued that this is due to the fact that place hypotheses hinder learning, since (a) they promote freezing in inescapable, dangerous places, and (b) they retard movement back into a dangerous compartment in which the animal has recently been shocked. In support of this view, it has been shown that manipulations that increase the discriminability of the two compartments of the shuttle box will exacerbate the intact animal's difficulties (see O'Keefe & Nadel, 1978, p. 301). The robust facilitation of learning the two-way task that occurs after hippocampal lesions are made offers added support; without the possibility of (maladaptive) place strategies, these rats acquire the task easily. In contrast to this debilitating effect of place learning, specific foreground CSs, especially if they act as directional cues that the animal can approach or avoid, will enhance learning.

The effects of preexposure on learning in the two-way task must be interpreted in terms of what is being preexposed and in terms of the role this component typically plays in learning. Preexposure to the place will reduce the likelihood of place strategies being used in any subsequent conditioning: By virtue of this preexposure the place becomes a relatively unreliable predictor of the US. Thus place preexposure should enhance solution of the two-way avoidance task. Preexposure to the specific cues will reduce their role in conditioning within that context because they will have been incorporated into the hippocampal representation of that environment, and there will be no misplace output to identify them as novel when they are reintroduced with the US. To put it another way, they will have been absorbed or embedded into the context and as a consequence, they are unlikely to be rapidly associated with the newly introduced US. Since such CSs normally enhance two-way avoidance

[3] McFarland et al. compared preexposed and nonpreexposed hippocampals and controls on their ability to form an aversion to a walnut solution paired with lithium carbonate. Their conclusion that hippocampal rats are deficient in LI was based on separate tests that were conducted with the walnut solution and tap water on the days immediately following poisoning. Inspection of their data reveals that the poisoning markedly depressed baseline water consumption of most of their rats. Any conclusions based on a comparison of water and walnut solution intakes are tenuous.

learning, their preexposure should act to retard it.

One major difference between the Ackil et al. (1969) and the Olton and Isaacson (1968) studies was in their control treatments for preexposure. In both studies, the experimental group was preexposed to background cues and specific foreground cues. However, this preexposed group was compared to different control groups in the two studies. Olton and Isaacson used a no-exposure control, whereas Ackil et al. used a place exposure control. This can be schematized as follows:

	Preexposed components		
	Place	Place + CS	Nothing
Olton & Isaacson	—	Experimental >	Control
Ackil et al.	Control >	Experimental	—

This layout shows the conditions used in the two studies, and the signs indicate the results. Preexposure to the place facilitates learning; preexposure to both place and CS facilitates learning somewhat less. This pattern of results makes sense within cognitive map theory, as does the absence of any preexposure effects in rats with hippocampal lesions.

Another paradigm discussed by Solomon is blocking. The basic procedure here involves first conditioning to one CS ($CS_A \rightarrow US$) and then presenting an added CS in compound with the pretrained CS during subsequent trials ($CS_ACS_B \rightarrow US$). The typical finding is that conditioning to CS_B is weaker than would occur in the absence of prior conditioning to CS_A. It is often said that because CS_B fails to predict anything not already predicted by CS_A, it is tuned out, and little conditioning occurs. There are defects in blocking in hippocampally lesioned subjects, as Solomon notes (Solomon, 1977; Rickert, Bennett, Lane, & French, 1978). There is as yet no fully accepted explanation of blocking.[4] In particular, the role of context in the development of blocking has yet to be determined. The present analysis predicts that it should have an important role, similar to that seen in LI. We treat this specific issue and provide further discussion of several Pavlovian paradigms, in another article (Nadel & Willner, Note 2).

Hippocampal Lesions and Conditioned Inhibition

A conditioned inhibitor (CS^-) is defined as a stimulus that as a result of certain prior experiences (specified later) (a) detracts from the efficacy of a CS known to elicit a conditioned response, and (b) itself conditions more slowly than in the absence of this prior experience (Rescorla, 1969). Rescorla and Wagner (1972; Wagner & Rescorla, 1972) have specified the conditions necessary to produce a CS^-: A CS will become a CS^- when it is negatively correlated with the US. That is, a stimulus will become an inhibitor when it signals a lower probability of US occurrence than the animal would otherwise expect.

According to Solomon (1979), it is precisely the fact that the CS^- signals a change in the conditions of reinforcement that prevents it from being tuned out, and this in turn prevents hippocampal lesions from having any effect on the establishment of conditioned inhibition. Solomon (1977) tested this notion in rabbits and found no differences between lesioned and control subjects. So far, these data appear to support Solomon's assertions. He also assumed that the spatial mapping theory predicts no general defects in this task. We agree with Solomon insofar as we feel that the hippocampus has no general inhibitory function. However, this does not mean that the hippocampus has no role in the learning process that underlies conditioned inhibition. To the extent that (spatial) context is important in the conditioning of inhibition, we expect defects in this paradigm in lesioned subjects. There are in fact a variety of procedures that will turn a CS into a CS^-, and it is useful to look at these procedures with

[4] Failures of blocking ("unblocking") can occur when the added CS is correlated with some change in stimulus conditions. For example, changes in US intensity (Kamin, 1969), or in the number of USs (Dickinson, Hall, & Mackintosh, 1976) produce unblocking. Brief, nonreinforced presentation of the CS_ACS_B compound also produces unblocking (Gray & Appignanesi, 1973). Interestingly, changes in the temporal duration (Kohler & Ayres, Note 1) or temporal patterning (Gray, 1978) of the CSs fail to produce unblocking. This set of results is not particularly congenial to a temporal mapping/tuning out interpretation of the hippocampal role in blocking.

an eye towards the role that place learning plays in each of them.

Solomon (1977) generated conditioned inhibition through the use of the classical Pavlovian procedure (Pavlov, 1927). In this procedure the animal receives trials in which CS_A is always followed by the US, interspersed with trials in which a compound of CS_A and CS_B is never followed by the US. As a result of this training, the added CS_B acquires substantial inhibitory properties (i.e., becomes a CS^-). In this preparation, an expectancy of the US is generated by the presentation of CS_A (the CS^+). When the compound of CS_A and CS_B is not followed by the US, this expectancy is not confirmed. The added CS becomes an inhibitor because it is correlated with the omission of an otherwise expected US. Background cues play little role in this case and hippocampal lesions accordingly have little effect.

However, there are other paradigms generating conditioned inhibition in which spatial context seems to be of greater importance, such as those in which the CS and US are explicitly unpaired or in so-called discriminative classical conditioning. In their analysis of conditioned inhibition, Wagner and Rescorla (1972) argued that the development of inhibition in these preparations is mediated by the context (place) in which conditioning occurs. That is, the expectancy of the US is generated by the place. Since the hippocampus is crucial to learning about places, we predict deficits in lesioned subjects when these paradigms are used. It is of some interest that the other published study on conditioned inhibition in hippocampal animals employed the discriminative conditioning procedure. Micco and Schwartz (1971) trained rats in a situation in which one CS (CS^+) was always followed by a shock US, whereas a second CS (CS^-) was never followed by the shock CS. They then tested these CSs on an avoidance baseline. In normal rats the CS^+ facilitated avoidance responding (presumably through enhanced fear), whereas the CS^- suppressed responding. Hippocampal rats, on the other hand, showed increased responding in the presence of the CS^+ but virtually no effects of CS^- presentation. In other words, when places are important in the development of conditioned inhibition, hippocampal lesions produce profound defects. It is important to note that tuning out plays no role in any of these conditioned inhibition paradigms, according to Solomon.[5]

Thus, the available data support Solomon's contention that the hippocampus is involved in certain Pavlovian procedures but fail to support his assertion that this involvement demands an enlarged view of hippocampal function that goes beyond space into time. Except for the untested case of blocking, spatial context has been implicated as an important factor in those conditioning paradigms in which hippocampal lesion effects have been demonstrated. Furthermore, a defect was seen in a version of conditioned inhibition training in which place learning is important but in which the tuning out of irrelevancy is not. In sum, then, the lesion data discussed by Solomon offer no strong reason to abandon the parsimonious view that the hippocampus is merely a spatial mapping system. Rather, the lesion data argue for a closer examination of the role of spatial context in tasks that have hitherto been thought of as relatively free of such influences.

Hippocampal Recording During NMR

A second line of evidence that Solomon cites to support his notion that the hippocampus is involved in NMR is the changes in hippocampal unit firing during NMR reported by Berger, Thompson, and their colleagues (Berger, Alger, & Thompson, 1976; Berger & Thompson, 1978a, 1978b; Thompson, 1976).

We have worried about the apparent discrepancy between the results of single-unit studies in the hippocampus of rat and rabbit. Most recent studies on the rat (e.g., Best & Ranck, 1975; Hill, 1978; O'Keefe, 1976; O'Keefe & Conway, 1978; O'Keefe & Dostrovsky, 1971; Olton, Branch, & Best, 1978) report that many hippocampal cells fire preferentially to one part of an environment (*place cells*). In contrast, studies on the rabbit do not report place cells but concentrate on the changes in unit firing during classical conditioning

---

[5] This analysis of the Micco and Schwartz study makes sense of what previously seemed to us an anomalous result (O'Keefe & Nadel, 1978).

(Thompson's group) or on the response of hippocampal units to simple sensory stimuli such as flashing lights and pure tones (e.g., Vinogradova, 1970, 1975, see also the discussion in Elliott & Whelan, 1978, pp. 173–175, 192, 197). There might be several reasons for this discrepancy. One is that the hippocampus has a different function in different species. Winson (1972) has produced a variation of this argument with respect to hippocampal theta. This appears to be the most radical solution, and we agree with Solomon that it is unlikely to be the case. More probably, the investigators of rabbit and rat are looking at different aspects of the cell responses or are looking at the same cells but interpreting their responses differently. Two concrete possibilities immediately spring to mind. One possibility is that the groups working on the rabbit record cells while the animal is restrained in a small featureless box. If there are place cells in the rabbit hippocampus, this is the worst possible environment in which to find them, and even if they did have fields in these environments, the testing procedures would not allow the experimenters to see this. A second possibility is that the theta cells in the rabbit might change their firing rates during arousal as well as during movement. Support for this idea can be drawn from the observation that theta occurs in the rabbit in response to sensory stimuli as well as during movement (e.g., Harper, 1971; Kramis, Vanderwolf & Bland, 1975).

To check these possibilities, O'Keefe (Note 3) has recorded units from fields CA1 and FD[6] of the hippocampus of the freely moving rabbit. Preliminary results show that there are both place cells and theta cells in the rabbit hippocampus. The rabbit place cells seem identical to those recorded in the rat, whereas the theta cells in the rabbit fire during arousal as well as during movement, in contrast to the rat's theta cells. Berger and Thompson (1978a) have reported on some of the physiological characteristics of the hippocampal cells that were involved in conditioning. Most of the units that were involved could be antidromically activated by electrical shocks to the fornix and (judging from the histograms presented) appeared to have high spontaneous rates. On the other hand, units not involved in conditioning could not be antidromically activated from the fornix; some were orthodromically activated while the rest were not affected at all. This latter group "tended to have very low spontaneous rates, sometimes showing interspike intervals as long as 60–120 sec" (p. 1574). The spontaneous rates suggest that this last group is composed of place cells, whereas the high firing cells involved in conditioning are primarily theta units. However, the finding that some of the units involved in conditioning can be antidromically activated from the fornix and are therefore probably pyramidal cells is not consistent with this analysis. There is evidence in the rat that the complex spike cells (into which category the place cells fall) and not the theta cells are the pyramidal cells (Fox & Ranck, 1975, 1977).

Hippocampal Stimulation During NMR

Finally, Solomon cites the stimulation studies of Salafia and his colleagues (Salafia, Chiaia, & Ramirez, 1979; Salafia, Romano, Tynan, & Host, 1977) as support for his tuning out hypothesis. Salafia found that stimulation of the hippocampus (and more recently the amygdala) after each CS–US pairing retarded conditioning of the NMR. Solmon thinks that stimulation could result in the tuning out of all stimuli, relevant or irrelevant, and in this way retard conditioning. How sound is this reasoning? Since hippocampal lesions have no effect on acquisition, Solomon must think that the stimulation is not producing a temporary lesion but is actively blocking sensory transmission. But in Salafia's studies the stimulation is given after both the CS and US have been presented and cannot have any role in tuning out either on that trial. The experiment that *would* support Solomon's tuning out hypothesis would be one in which hippocampal stimulation during or just prior to the CS retarded conditioning, whereas stimulation at other times had no effect. Stimulation after the trial would be a control condition designed to rule out general stimulation effects, consolidation effects, prograde effects, and so forth. In general, we suggest caution in the

[6] CA1 = cornu ammonis 1, FD = fascia dentata.

interpretation of stimulation effects, since they can affect wide areas of the brain and when afterdischarges are involved, can cause long lasting changes in distant synapses (Goddard, McIntyre, & Leech, 1969; Racine, 1972).

In summary, Solomon has called attention to a set of data on classical conditioning that we have not previously dealt with adequately and that he felt lay outside the explanatory domain of the hippocampal cognitive map theory. He suggested that the theory is inadequate and needs to be extended to include temporal as well as spatial mapping. One of the functions of the temporal map would be to tune out irrelevant stimuli. Although we have considered elsewhere the possibility that the time at which an episode occurred might be indirectly coded in the mapping system (see O'Keefe & Nadel, 1978), this is a different type of temporal coding from the short-term temporal sequencing between stimuli invoked by Solomon.

We have looked carefully at the conditioning literature that Solomon cited and concluded that with the exception of blocking, the cognitive map theory handles the results adequately. Whether or not it can also handle blocking must await experiments designed to elucidate the role of place learning in this paradigm.

Type I Error Rate of the Chi-Square Test of Independence in $R \times C$ Tables That Have Small Expected Frequencies

Drake R. Bradley, T. D. Bradley, Steven G. McGrath, and Steven D. Cutcomb
Bates College

Sampling experiments are reported which show that the uncorrected chi-square test of independence is exceptionally robust with respect to small expected frequencies in $R \times C$ contingency tables. In 2×2, 2×3, 3×3, 3×4, and 4×4 tables, the actual Type I error rates did not exceed .06 ($\alpha = .05$) for those applications most likely to arise in practice. In general, error rates that exceeded .06 occurred only when both marginal probability distributions were extremely skewed and sample size was small. Nevertheless, the quality of the approximation of chi-square probabilities for exact multinomial probabilities was sometimes poor, although excessive errors in approximation by Cochran's criteria usually resulted from actual error rates being smaller, not larger, than the nominal level. A distinction is made between accuracy of approximation and control of the Type I error rate as considerations dictating the advisability of using an approximate test.

In 1949 Lewis and Burke published an article entitled "The Use and Misuse of the Chi-Square Test." These authors argued that social scientists frequently misused the chi-square test and that the most common error in applying the test to contingency tables resulted from "the use of extremely small theoretical frequencies" (Lewis & Burke, 1949, p. 460). Rebuttals by Peters (1950), Pastore (1950), and Edwards (1950) did little to resolve the developing controversy, and recent publications (Tate & Hyer, 1973; Tate & Hyer, Note 1) demonstrate that the issue of "how small is small?" is still unresolved today. The issue arises, of course, because the chi-square distribution provides only approximate estimates of exact multinomial probabilities. The quality of this approximation depends in a complex way on sample size, the true distribution of marginal probabilities in the population, the number of cells in the contingency table, and the level of significance employed. Consequently, it is extremely difficult to formulate simple rules of thumb that indicate when the approximation is adequate and when it is not.

Cochran (1952) suggested that the approximation is satisfactory if the actual Type I error probabilities remain between .04 and .06 for tests conducted at $\alpha = .05$ or between .007 and .015 for tests conducted at $\alpha = .01$. Given any such specific criteria, the traditional approach has been to seek a minimum expectation that delimits the lower bound beyond which the approximation is no longer satisfactory. Although there is no commonly accepted rule of thumb for deciding when expected frequencies are too small, many investigators accept Hays's recommendation (1963, p. 584, 597) that for applications involving one degree of freedom, the minimum should be set at 10, whereas for other applications a minimum of 5 is sufficient. Under some circumstances a minimum expectation of 2, 1, or even fractional expectations may be permissible according to some authors (Cochran, 1952, 1954; Good, 1961; Slakter, 1965, 1966;

The authors wish to acknowledge the excellent service provided by the Dartmouth Time-Sharing system, which was used to conduct the computer simulations reported in this article.

Requests for reprints should be sent to Drake R. Bradley, Department of Psychology, Bates College, Lewiston, Maine 04240.

Vessereau, 1958; Wise, 1963; Yarnold, 1970). However, it has been recently suggested that a minimum expectation of 20 is necessary to ensure that the approximation will be accurate under all circumstances (Tate & Hyer, 1973). Unfortunately, the absence of a strong consensus on this matter makes it extremely difficult for the researcher to know if he or she is employing the chi-square statistic properly.

A related issue concerns the use of a continuity or similar correction to improve the approximation. There has been a continuing controversy over whether such corrections are necessary or desirable in all instances, and assuming that they are, over which method of correction provides the best approximation (Boschloo, 1970; Camilli & Hopkins, 1978; Conover, 1974; Garside, 1971, 1972; Garside & Mack, 1970, 1976; Grizzel, 1967; Larntz, 1978; Mantel, 1974; Mantel & Greenhouse, 1968; Miettinen, 1974; Nass, 1959; Plackett, 1964; Starmer, Grizzel, & Sen, 1974; Yates, 1934). Part of the controversy results from differences in opinion as to what constitutes a good approximation. Some authors insist that whatever correction is used, the actual Type I error probability should be maintained at a level less than or equal to α (Mantel & Greenhouse, 1968). Others argue that the correction should simply minimize the absolute difference between the true and nominal values. The latter technique, although it permits some inflation in the Type I error rate, may often be more accurate than the former. There has also been disagreement as to whether so-called exact tests provide the appropriate standard for evaluating the ability of approximate tests to control the Type I error rate at the nominal level (Starmer et al., 1974). This issue arises because the exact test may not provide a test with a predetermined significance level as high as the desired nominal value (Garside & Mack, 1976; Starmer et al., 1974) unless it is supplemented by randomization techniques (Tocher, 1950). If so, continuity corrections based on the exact test as the standard may be unnecessarily conservative.

Indeed, a number of Monte Carlo studies have shown that the chi-square test is relatively robust with regard to violations of the minimum expected frequency requirement, even when the test is uncorrected. Slakter (1966) found that the chi-square test was robust in goodness of fit to uniform applications even with fractional expected frequencies. Lewontin and Felsenstein (1965) investigated the $2 \times K$ case in a uniform population and where both row and column marginal frequencies remained fixed and found that the chi-square test was robust over the range of values tested. Roscoe and Byars (1971) extended Slakter's findings to a wider range of N (sample size) and K (number of categories) as well as to nonuniform distributions. In addition, they extended Lewontin and Felsenstein's results to contingency tables that had rows and columns in all combinations of 2 to 5, although they elected to fix only the row marginal frequencies. They found that the chi-square test was exceptionally robust in goodness of fit to uniform applications and in tests of independence with more than one degree of freedom. Finally, Bradley and Cutcomb (1977) and Camilli and Hopkins (1978) have shown that for selected sets of 2×2 tables in which neither row nor column marginals were fixed, the chi-square test of independence is highly robust to violations of minimum expected cell frequency. The results of these various Monte Carlo studies suggest that the minimum expected frequency requirement can be relaxed considerably.

In this article we report the results of a comprehensive set of sampling experiments that evaluate the Type I error rate of the chi-square test of independence in $R \times C$ contingency tables. The simulations reported here differ from previous numerical or Monte Carlo studies on $R \times C$ contingency tables (Camilli & Hopkins, 1978; Garside & Mack, 1976; Kurtz, 1968; Larntz, 1978; Lewontin & Felsenstein, 1965; Roscoe & Byars, 1971; Starmer et al., 1974) in that (a) the sample sizes and marginal probability distributions that were selected range over all values likely to arise in practice, and/or (b) neither the row nor column marginal frequencies were fixed. The second feature is intended to model the most common application of chi-square to $R \times C$ tables; that is, N elements are randomly sampled from a population and classified on each of two polychotomous variables, thereby producing a table in which the row and

Method

Actual Type I error rates for the chi-square test in 2×2, 2×3, 3×3, 3×4, and 4×4 tables were determined by sampling experiments conducted on a Honeywell 66/40 duplex computer. For any given simulation, the joint probability distribution was obtained by multiplying row and column marginal probabilities: $P(RC_{ij}) = P(R_i)P(C_j)$. A pseudorandom number generator (linear congruence method) sampled N numbers between 0 and 1 from a uniform distribution, and each such number was used to place a count in one of the cells of the $R \times C$ table via reference to the cumulative joint probability distribution (see Lehman, 1977, p. 166). The chi-square test of independence (Hays, 1963, p. 591) was conducted on the resulting contingency table, using the empirically sampled marginal frequencies to compute the expected frequency of each cell.[1] This procedure was repeated for a total of 10,000 samples per simulation, and the proportion of significant chi-square tests that were obtained provided the estimate of the Type I error rate.

Each $R \times C$ table was investigated for a large number of marginal probability distributions ranging from uniform to highly skewed on both rows and columns and including all combinations (in .10 increments) in between. For example, 2×2 tables were investigated for row and column marginal probabilities ranging from .5, .5 and .5, .5 (uniform on both) to .9, .1 and .9, .1 (highly skewed on both). All combinations in between these extremes, in .10 increments (.5, .5 and .6, .4; .5, .5 and .7, .3; etc.), were investigated. Similarly, in 3×4 tables the marginal probabilities ranged from $\frac{1}{3}$, $\frac{1}{3}$, $\frac{1}{3}$, and .25, .25, .25, .25 (uniform on both) to .8, .1, .1 and .7, .1, .1, .1 (highly skewed on both). Every $R \times C$ marginal probability distribution was investigated at $\alpha = .05$ and $N = 20$, 40, 60, 80, 100, and 200. In addition, all 2×3 and 3×3 tables were investigated for $N = 10$, all 3×4 and 4×4 tables were investigated for $N = 30$, and all 2×2 tables were investigated for $N = 4$, 10, 400, and 1000. Finally, all 2×2 tables were also investigated at the $\alpha = .01$ and .10 levels of significance.

Fifteen combinations of marginal probabilities were investigated for 2×2 tables, 45 for 2×3 tables, 45 for 3×3 tables, 90 for 3×4 tables, and 55 for 4×4 tables. Given a grand total of 250 unique $R \times C$ marginal probability distributions and the various sample sizes and α levels that were investigated, 2095 individual simulations were conducted to evaluate the actual Type I error rates of the chi-square statistic in $R \times C$ contingency tables.

Results

Due to space limitations, complete tables of the Type I error rate of chi-square in 2×2, 2×3, 3×3, 3×4, and 4×4 tables cannot be presented here.[2] Table 1 presents Type I error rates for those marginal probability distributions in which one or more error rates fall outside the interval .03–.06 ($N \geq 20$ and $\alpha = .05$).[3] Hence, Table 1 summarizes those conditions in which the errors of approximation might be considered excessive. Note that we have not employed Cochran's (1952) suggested interval of .04–.06 in constructing Table 1. Although the use of an asymmetrical interval (.03–.06) was motivated partly by the requirement to present the data in highly condensed form (errors of approximation in the .03–.04 region were fairly common for $N = 20$), the asymmetry also parallels that implicitly endorsed by most investigators, namely, that errors of approximation of any given magnitude are generally more tolerable when they err in the direction of conservatism.[4]

---

[1] On occasion, a sampled table might contain one or more expected frequencies equal to zero; if so, the corresponding cells were bypassed in the computation of the total value of chi-square to prevent division by zero.

[2] Some of the data discussed in this report are reproduced in Bradley and Cutcomb (1977) and Bradley, McGrath, and Bradley (1978), and were presented at the 1977 Eastern Regional Meeting in Chapel Hill, North Carolina, and the 1978 Annual Meeting in San Diego, California, of the American Statistical Association.

Unabbreviated tables of Type I error rates are available from the first author.

[3] As a check on the Monte Carlo procedure used, the empirical estimates can be compared to the exact probabilities of a Type I error computed for 2×2 tables based on small N. Consider, for example, an N of 4 and a marginal probability distribution of .5, .5 and .5, .5: manual expansion of the multinominal results in an exact probability of .1094 of sampling a table which will produce a chi-square statistic significant at the .05 level or better. The corresponding sampling experiment produced an empirical estimate of .1089, which agrees with the exact value within the limits of error ($\sigma_p = \sqrt{p(1-p)/K}$, where $K = 10{,}000$ trials). Similar checks for the remaining 2×2 marginal probability distributions that were investigated showed the empirical estimates to be in good agreement with the exact values.

[4] Of course, the investigator must also be concerned with maintaining adequate power in conducting tests of independence in situations in which errors of approximation may result in differences between actual and nominal power. Bradley and Seely (1977) have developed power tables for the 2×2 case that because they are based on empirical simulations, automatically incorporate the effect of errors of approximation on the power of the chi-square test.

The increased probability of making a Type I error is usually of greatest concern, and for this reason we have used the same upper limit (.06) for our interval as that used by Cochran (1952).

Several trends may be noted with respect to the data presented in Table 1. First, excessive inflation in the Type I error rate ($p > .06$) tends to be a problem when both marginal probability distributions of the $R \times C$ table are highly skewed (e.g., rows 1, 2, 4, 9, and 14). Conversely, excessive deflation in the Type I error rate ($p < .03$) tends to be a problem when one marginal distribution of the $R \times C$ table is highly skewed and the other is relatively uniform (e.g., rows 15, 17, 22, 27, and 36). Finally, marginal probability distributions that are uniform (or nearly uniform) on both rows and columns do not result in excessive errors of approximation, even when minimum expected frequency requirements (of 5 or 10) are violated in all $R \times C$ cells of the table, as often occurs for $N = 20$. [Theoretical expected frequencies may be obtained by computing $P(R_i)P(C_j)N$ for each cell of the table.]

The error rates represented in Table 1 pertain to tests conducted at $\alpha = .05$. As noted earlier, simulations were also conducted for $\alpha = .01$ and .10 for 2×2 tables. Although the trends discussed previously were clearly evident in the error rate data for $\alpha = .01$ ($N \geq 20$), they were less apparent in the data for $\alpha = .10$.[5]

Discussion

These results might or might not imply a "liberalized" policy with regard to using the chi-square test on tables that have small expected frequencies. Since errors of approximation can be fairly substantial, with actual error rates ranging from .0187 to .0891 for $N \geq 20$ and $\alpha = .05$ (rows 17 and 4 of Table 1), some investigators might elect to maintain a conservative policy with respect to using the chi-square test (see Tate & Hyer, 1973). However, traditional rules of thumb based on minimum expected frequency, without regard to the marginal distributions, do not provide selective protection against errors of approximation where such protection is needed most (Table 1). That is, these rules of thumb will often prohibit the use of the chi-square test in situations in which it provides a satisfactory approximation. Furthermore, it can be argued that accuracy of approximation per se is not the central issue in determining the advisability of using the chi-square test. Rather, the key issue for many investigators is the ability of this test to control the Type I error rate at or below some acceptable upper limit, α', relative to the nominal level, α.

The sampling experiments reported here show that for the large majority of applications likely to arise in practice, the actual Type I error rates will not exceed $\alpha' = .06$ for tests conducted at the nominal level of $\alpha = .05$.[6] This is true without any correction for continuity and regardless of the size and number of small expected frequencies in the $R \times C$ table. For the few exceptions that are noted in Table 1 ($p > .06$), in which row and column probabilities are both highly skewed, the investigator can simply select a more conservative alpha level for conducting the test. Since the maximum inflation in error rate for $N \geq 20$ is less than double the nominal value, using an adjusted level of $\alpha/2$ should suffice in most cases for the provision of adequate protection at the original level desired.

The preceding arguments do not, of course, imply that when the investigator consults a table of chi-square to determine the specific level of significance of an outcome, the tabled value will provide an accurate approximation to the exact multinomial probability. Tate and Hyer (1973) are correct in noting that these values can differ substantially. Never-

[5] To investigate in more detail the effect of small sample size on errors of approximation, additional sampling experiments were conducted at $\alpha = .05$ for a 2×2 table with marginal probabilities of .8, .2 and .9, .1. Actual Type I error rates were obtained for all sample sizes between and including $N = 4$ and $N = 40$. The Type I error rates ranged from .0203 ($N = 7$) to .0589 ($N = 20$).

[6] For $\alpha = .01$ (2×2 tables) a parallel conclusion is reached, namely, that for the large majority of applications likely to arise in practice, the actual Type I error rates will not exceed $\alpha' = .015$ (Cochran's upper limit) for tests conducted at the $\alpha = .01$ level. As in Table 1 (row 1), the only exception to this generalization was the .9, .1 and .9, .1 marginal probability distribution.

theless, as long as the null hypothesis can be tested at some maximum specifiable level of risk, inaccuracy of approximation on either side of the rejection point need not concern the investigator, if his or her only interest is in making a decision about the presence of association in the $R \times C$ table and not in estimating exact cumulative multinomial probabilities. In this context, it seems unreasonable to prohibit the use of a convenient statistical test on the basis of inaccuracies in approximation over regions of the distributions that are largely irrelevant to the decision-making behavior of the investigator.

In conclusion, if the investigator's main concern is in controlling the Type I error rate or below some acceptable upper limit ($\alpha' = .06$), then the computer simulations reported in this article show that the chi-square test of independence may be safely used in nearly all situations likely to arise in practice. If this conclusion is correct, then the frequent abuse by social scientists of the minimum expected frequency requirement that was first reported by Lewis and Burke in 1949 will turn out not to be a "misuse" of the chi-square test at all. Instead, it will simply illustrate another instance in which "the results of theory sometimes remain substantially true even when some assumptions fail to hold" (Cochran, 1952, p. 328).

Home-Based Reinforcement Programs Designed to Modify Classroom Behavior: A Review and Methodological Evaluation

Beverly M. Atkeson and Rex Forehand
University of Georgia

The present article reviews and evaluates the current research on the use of home-based reinforcement programs to modify both disruptive and academic behaviors in the classroom. This treatment program has been used with a variety of students, settings, and behaviors, and the results have been positive. However, the conclusions concerning the effectiveness of home-based reinforcement programs are limited because of the methodologies used in the studies that are reviewed.

Over the past 10 to 15 years, the role of the behavioral psychologist who works with children has gradually changed from that of direct change agent to that of consultant. More and more frequently, parents are trained as behavior therapists for their child's problems. Recent reviews indicate that this is an effective and efficient treatment approach (Berkowitz and Graziano, 1972; Graziano, 1977; Johnson & Katz, 1973; O'Dell, 1974). In the field of education, a similar shift has occurred. There is now substantial experimental evidence which indicates that teachers themselves can function as behavior modifiers in the classroom and can deal with a wide variety of problems (O'Leary & O'Leary, 1976, 1977b).

More recently, an increasing number of studies have tried to join the teacher and parent in a cooperative effort to reduce problems in the school setting. The present article reviews the current research on the use of home-based reinforcement programs designed to modify classroom behaviors. Basically, with this procedure the teacher is responsible for specifying the classroom rules, for determining rule violations, and for communicating these to the parent. At home the parent is responsible for consistently dispensing rewards and sanctions to the child, based on the teacher's report.

For purposes of presentation, the articles reviewed have been organized into two areas, based on the classroom behaviors that were targeted for treatment. The first section reviews the research on home-based reinforcement programs designed to modify disruptive behaviors in the classroom, and the second section reviews those designed to change academic behaviors in the classroom. Following the presentation of the current research, the third section of the article examines the methodology used in the studies to evaluate the reported results and to determine future areas of research.

Disruptive Behaviors in the Classroom

Although specific behaviors labeled as disruptive may vary from teacher to teacher, in general they are behaviors that the teacher views as disruptive to the learning process in his or her classroom; these may include making noise, talking without permission, physically disturbing other children, and getting out of one's seat without permission.

This article is an expanded version of part of an article by Atkeson and Forehand entitled "Parents As Behavior Change Agents With School-Related Problems," which appeared in *Education and Urban Society* (*10*, 521–538).

Preparation of this manuscript was supported in part by National Institute of Mental Health Grant MH28859-01.

Requests for reprints should be addressed to Rex Forehand, Department of Psychology, University of Georgia, Athens, Georgia 30602.

Unfortunately, these behaviors often demand a great deal of the teacher's time. In fact, when teachers were asked to identify classroom behaviors to change, 80% chose to reduce the occurrence of a "bad" behavior (O'Leary & O'Leary, 1977a).

Teachers have successfully used a number of behavioral techniques to decrease disruptive behaviors in the classroom. These include (a) increasing incompatible behaviors (e.g., on-task behavior, sitting still, correct academic performance) through the use of contingent tangible rewards and/or social praise, (b) punishing disruptive behaviors (e.g., with loss of privileges and/or brief isolation of the child), and (c) dispensing tokens (e.g., check marks or chips) for following classroom rules or for meeting a specified level of academic performance, redeemable for backup reinforcers in the classroom (O'Leary & O'Leary, 1977b). Although highly effective, the above procedures do have some disadvantages. To be successful, each procedure may require a great deal of time and effort on the part of the teacher and behavioral consultant (Schumaker, Hovell, & Sherman, 1977). Often the teacher must alter her/his own teaching style to reduce the misbehavior of only a few students (Schumaker et al., 1977). In addition, the tangible rewards or backup reinforcers available are often limited in the classroom (Ayllon, Garber, & Pisor, 1975; Schumaker et al., 1977). In contrast, parents often have access to a wide variety of privileges (e.g., allowances, TV time, movies, skating) not available to most teachers (Ayllon et al., 1975; Bailey, Wolf, & Phillips, 1970; Karraker, 1972).

In an attempt to lessen the above disadvantages, psychologists have used some variation of a home-based reinforcement program to reduce the disruptive behavior of one or more children in a classroom. In these studies the content or degree of specificity of the teacher's report to the parents has varied from global to detailed. Some teachers were asked to send a note stating only whether the child was good (Ayllon et al., 1975; Heaton, Safer, Allen, Spinnato, & Prumo, 1976). More frequently, the note home listed the classroom rules and whether the child followed each of the rules (Hawkins, Sluyter, & Smith, 1972, Experiment 4; Lahey et al., 1977; Schumaker et al., 1977). Although both the global and specific reports to the home produced the desired change, there have been no studies that directly compared the two approaches. Each, of course, has its own advantages and disadvantages. The more global report may be somewhat quicker for the teacher to complete but may also be less objective. Stating each classroom rule on the note communicates more information to both the child and the parents. Three studies (Bailey et al., 1970; Clark, 1972; Kirigin, Bailey, Phillips, Fixen, & Wolf, Note 1) provided a compromise between global and detailed reports. At the beginning of the program, the teacher listed the classroom rules on the board so that they were clearly stated for the child. The daily report home, however, indicated only whether the student obeyed class rules.

In most studies, the teacher–parent communication occurred daily. Three studies, however, sent notes home only when the child was good (Ayllon et al., 1975; Hawkins et al., 1972, Experiment 4; Heaton et al., 1976), the rationale being that a note communicating misbehavior might never reach home (Ayllon et al., 1975). Only one study limited the parent–teacher communication to a weekly contact (Coleman, 1973). Although this was successful at maintaining the student's good behavior, the teacher had previously used other behavioral techniques to establish the desired behaviors in the classroom before instituting the weekly communication home. One would expect that the more frequent the communication between school and home, the more rapid the behavioral change.

Several studies did report that some students lost their notes before reaching home. The approach by Ayllon et al. (1975), Hawkins et al. (1972, Experiment 4), and Heaton et al. (1976) of sending notes home only when the report is good is one way to circumvent this problem, since such a procedure should increase the child's motivation for carrying the note home. However, this technique does not guarantee that a note will reach home. If the rewards dispensed at home are not potent enough, the note's importance to the child is diminished, and the note may be lost (Schumaker et al., 1977). Of course, the parents can be required to call the teacher to obtain

the necessary information if the note fails to reach home (Kroth, Whelan, & Stables, 1970). In fact, two studies used the telephone exclusively for the teacher–parent communications (Coleman, 1973; Strober & Bellack, 1975). Although this approach completely circumvents the problem of missing notes, it does require more time on the part of the teacher.

The rewards received by students at home for good behavior at school varied from verbal praise (Lahey et al., 1977; Schumaker et al., 1977, Experiment 2) to tangible rewards such as allowances (Coleman, 1973; Heaton et al., 1976) and certain privileges (Bailey et al., 1970; Clark, 1972; Hawkins et al., 1972, Experiment 4; Heaton et al., 1976; Schumaker et al., 1977; Strober & Bellack, 1975; Kirigin et al., Note 1). Some studies did not include sanctions at home for misbehavior at school (Hawkins et al., 1972, Experiment 4; Lahey et al., 1977). When included, sanctions usually involved loss of certain privileges such as TV, snacks, or a later bedtime (Ayllon et al., 1975; Clark, 1972; Heaton et al., 1976; Strober & Bellack, 1975). In the study by Todd, Scott, Bostow, and Alexander (1976), 3 successive "undesirable" days resulted in a 1-day suspension from school, a rather extreme punishment in our opinion.

In the study by Lahey et al. (1977), contingent parental praise at home, implemented for all children in two kindergarten classrooms, was sufficient to reduce school disruptive behavior. In contrast, Schumaker et al. (1977, Experiment 2) found that parental praise was initially effective with one disruptive adolescent but not with another. The second adolescent's school behavior did not improve until home privileges were added to parental praise. In addition, the initial improvement in the behavior of the first adolescent appeared to decline over time. A key difference in the Lahey et al. and Schumaker et al. studies is the age of the students; parental praise may be more effective the younger the student. The Schumaker et al. study is the only one that has attempted to compare different consequences (praise vs. praise plus privileges in this case) in the home. More studies are needed that examine the specific effects of praise, tangible rewards, and sanctions when used by parents as consequences for disruptive behavior at school and that examine how each of these interacts with the demographic variables (e.g., age, socioeconomic status) of the subject.

Of special importance is the wide variety of students with which some type of home-based reinforcement program has been effective in reducing disruptive behavior in the classroom. It has been used successfully with children of all ages, from elementary school to high school. The students in the studies reviewed were frequently more than 1 year behind in academic skills (Ayllon et al., 1975; Schumaker et al., 1977), had previous records of severe misconduct (Heaton et al., 1976), and were labeled as emotionally disturbed (Coleman, 1973) or underachievers (Hawkins et al., 1972, Experiment 4). Home-based reinforcement programs have even proven to be effective with delinquents in both special and regular classrooms (Bailey et al., 1970; Martin, Burkholder, Rosenthal, Tharp, & Thorne, 1968; Kirigin et al., Note 1).

Academic Behaviors in the Classroom

Academic behaviors include listening to presentations by the teacher, listening and participating in class discussions, asking and answering questions, working with eyes and head oriented toward materials, completing classwork neatly and correctly, and achieving (i.e., grades) appropriate to potential. As with disruptive behaviors, teachers have successfully used a number of behavioral techniques to improve the academic behavior of one or more students in their classroom (O'Leary & O'Leary, 1976, 1977b). Although effective, these procedures have the same limitations as those mentioned in the previous section. Not surprisingly, psychologists have successfully applied the same home-based reinforcement program that is used with disruptive behaviors to improve academic behaviors in the classroom. In fact, the use of this technique in the studies reviewed was rarely limited to either disruptive behaviors or academic behaviors. More often, some disruptive and some academic behaviors were included together in the teacher–parent communication (e.g., Bailey et al., 1970; Cohen,

Keyworth, Kleiner, & Libert, 1971; Lahey et al., 1977; Schumaker et al., 1977).

As might be expected from the large number of academic behaviors described earlier, the studies reviewed differed widely in their criteria for "good academic behavior." Some studies focused on behaviors that are considered conducive to learning (e.g., orienting eyes and head to work, looking at teacher, and responding to questions); a good teacher-to-parent report in this case indicated that the student had engaged in specific appropriate academic behaviors during class (Bailey et al., 1970; Coleman, 1973; Kirigin et al., Note 1). Other studies chose completion of classwork as the target for improvement and required the student to complete all classwork to receive a good report (Cantrell, Cantrell, Huddleston, & Wooldridge, 1969, Case 1; Harris, Finfrock, Giles, Hart, & Tsosie, 1975; Lahey et al., 1977). Several studies required not only classwork completion but also a certain level of achievement for a good report (Hawkins et al., 1972, Experiments 1–3; Stuart, 1971; Kirigin et al., Note 1; Kirigin et al., Note 2).

Although potentially effective, the use of a certain level of achievement on classwork as the criterion for good academic behavior at school and as the basis for parental consequences at home can produce certain problems. If the level of achievement is set too high, the student may be unable to meet the criterion. As a consequence, he or she has been placed in a "can't win" situation and, no matter how motivated initially, may never be able to receive any of the home rewards. Of course, a teacher–parent communication of this type would be unlikely to bring about the desired changes in the student's academic behavior.

Several studies have successfully handled the problems associated with the use of achievement level in the teacher–parent communication. In the study by Kirigin et al. (Note 2), two of the three female delinquents had no difficulty when good academic behavior and subsequent rewards at home were based on number of problems correctly done. In fact, the two girls improved their daily grade from a D to a B and a D to a C, respectively. The third female delinquent, however, showed no change in her academic behavior, even after the teacher–parent communication had been in effect for a week. When tutoring was included in the program, her accuracy on daily assignments quickly improved from an F to an A.

The home-based reinforcement program used by Hawkins et al. (1972, Experiments 1–3) provides another possible solution for using a criterion of achievement level with students performing below grade level. In their study the initial accuracy criterion for good academic behavior was placed at a level commensurate with the student's current performance. Each day the criterion was gradually adjusted upward with remarkable success.

As with disruptive behaviors, the content or degree of specificity of the teacher's report to the parents varied from global to detailed. Usually it was global, with teachers indicating only whether the student "studie[d] the whole period" (Bailey et al., 1970), "did very well" (Hawkins et al., 1972, Experiments 1–3; Heaton et al., 1976; Karraker, 1972) or "completed all his work" (Lahey et al., 1977). The study by Cantrell et al. (1969, Case 1) is an example of the other extreme. The teacher–parent communication indicated whether the student's class assignments were completed, were well-done, and had no more than two careless errors, whether the student listened to and complied with directions, and what daily grades were earned by the student. As with disruptive behaviors, there have been no studies that systematically examined the importance of degree of specificity of the teacher's report on the student's academic improvement.

In most studies that dealt with academic behaviors in the classroom, the teacher–parent communication occurred daily (e.g., Bailey et al., 1970; Karraker, 1972; Kroth et al., 1970; Schumaker et al., 1977; Kirigin et al., Note 1, Kirigin et al., Note 2). Some studies sent notes home only when the student displayed "good" academic behavior (Hawkins et al., 1972, Experiments 1–3, Heaton et al., 1976); others limited the teacher–parent contact to once a week (Coleman, 1973; Harris et al., 1975; McKenzie, Clark, Wolf, Kothera, & Benson, 1968). Again, there have been no studies that examined the frequency of teacher–parent

contact on the effectiveness of the home-based reinforcement programs.

A recent study did compare the effects of fixed-time and variable-time teacher–parent communications on the academic behavior of 26 third-grade students (Saudargas, Madsen, & Scott, 1977). Under the fixed-time condition, each student received a report for his/her parents on Friday that indicated the quantity and quality of her/his work completed that week. Under the variable-time condition, the same information was communicated to parents, but seven to nine students were randomly selected each day to receive a report to take home. The results show that more assignments were correctly completed when the students were unsure whether they would receive a report that day; that is, their academic output was higher under the variable-time condition. A similar study comparing daily to weekly teacher–parent communications is certainly needed.

The rewards and sanctions received by students at home for good academic behavior at school were similar to those in the previous section. Nearly all of the studies used home privileges (e.g., allowance, TV time, snacks, late bedtime) to reward a good teacher report (e.g., Bailey et al., 1970; Karraker, 1972; Schumaker et al., 1977). Two studies limited the rewards received at home to allowances (Coleman, 1973; McKenzie et al., 1968). This is perhaps simpler for parents to operate or at least less disruptive to family routines in that parents do not have to monitor such activities as TV time, bedtime, and so forth. Sanctions, when included, were limited to loss of privileges and were always used in combination with a reward system. As with the consequences for disruptive behaviors, more studies are needed to examine the effectiveness of different reward and punishment programs in changing academic behaviors.

Home-based reinforcement programs have been successful in increasing the academic behavior of a wide variety of students. As might be expected, the students in the studies reviewed were frequently described as under-achievers or as poorly motivated (Hawkins et al., 1972, Experiments 1–3; Karraker, 1972). Often the students were behind more than 1 year in several academic subjects (e.g., Schumaker et al., 1977). Of particular interest is the study by McKenzie et al. (1968). The students in their study had all been labeled as having learning disabilities.

Home-based reinforcement programs have also been used to increase academic behavior with students whose major difficulties may not be academic achievement. Several studies included students who had been labeled emotionally disturbed by teachers and/or mental health professionals (Coleman, 1973; Kroth, 1970). Other types of students included those considered to be moderate to severe discipline problems at school (Heaton et al., 1976; Schumaker et al., 1977; Strober & Bellack, 1975) and those considered to be delinquents by the community (Bailey et al., 1970; Harris et al., 1975; Martin et al., 1968; Stuart, 1971; Kirigin et al., Note 1, Kirigin et al., Note 2).

Methodological Evaluation

All of the studies reviewed present results that support the position that home-based reinforcement programs provide an effective treatment approach to modify both disruptive and academic behaviors in the classroom. This type of treatment has the added advantages of minimizing the time required by the teacher for implementation and involving the parents as change agents for their child's classroom behaviors. But before a complete endorsement of this treatment approach can be made, a more rigorous assessment of the research is needed to evaluate the validity of the results and to delineate areas for further investigation. To organize the critique of the studies reviewed, six categories (i.e., adequate design, systematic variation of treatment, multiple-outcome measures, follow-up, school program monitored, and home program monitored) that were deemed critical for sound research, were determined, and the articles were evaluated in terms of whether they met the requirements of each category. Four additional descriptive categories (i.e., sample size, grade, classroom setting, and target behavior) were included to assess the applicability of the results to different populations and settings. A summary of this evaluation is presented in Table 1.

Descriptive Categories

Regarding the descriptive categories, the number of subjects participating in the experiments varied from 1 to 124. The mean, median, and mode were 10.8 subjects, 2 subjects, and 1 subject, respectively. Subjects were from the primary grades (kindergarten through 6th) in 45% of the experiments and from the secondary grades (7th–12th) in the remaining 55% of the investigations. Sixty-eight percent and 32% of the experiments occurred in regular and special (e.g., remedial, emotionally disturbed, learning disability) classrooms, respectively. In 39%, 19%, and 42% of the investigations, academic (e.g., listening to presentations by teacher, asking and answering questions, working with eyes and head oriented towards materials, completing classwork, achieving, making good grades), disruptive (e.g., making noise, talking without permission, physically disturbing other children, getting out of one's seat without permission), and combined academic and disruptive behaviors, respectively, were targeted. These data indicate that most of the studies have involved few subjects; however, the programs have been implemented in all grades, in regular as well as special classrooms, and with both academic and disruptive behaviors.

Adequate Design

A major concern in evaluating the soundness of the studies reviewed is the adequacy of the experimental design that was used to examine treatment effects. The use of any of three types of designs was considered an adequate basis for the conclusion that the results were due to the experimental treatment. These were (a) ABA design (or some variation thereof with baseline and reversal), (b) multiple baseline design, and (c) group design with appropriate control group. If the experimental design of a study was one of the three above and there was not the confound of multiple interventions (e.g., home- plus school-based programs), the design was considered rigorous enough for the conclusion that the results were indeed due to the home-based reinforcement treatment program and not due to alternative factors.

Only 63% of the studies reviewed had adequate designs without multiple interventions (Table 1). Of these, the most frequently chosen design (10 of 17 or 58.8%) was some variation of the ABA design (e.g., Ayllon et al., 1975; Bailey et al., 1970). Only one study (Harris et al., 1975) selected a group design with an appropriate control group to examine the effects of home-based treatment programs. The studies with inadequate designs were usually studies with baseline and treatment data but no treatment reversal (e.g., Cantrell et al., 1969; Hawkins et al., 1972; Strober & Bellack, 1975). One study was considered inadequate because the home-based reinforcement program was confounded by being part of a larger multiple intervention treatment program. Conclusions about the effectiveness of home-based reinforcement were reached in spite of the confound (Coleman, 1973).

Systematic Variation of Treatment

A second criterion that was selected to evaluate the reviewed studies is the inclusion of systematic variation of treatment variables in the experimental design (i.e., component analysis). This is necessary if one is to differentiate which of the many variables that make up a treatment program are actually responsible for the observed changes (e.g., social vs. tangible rewards). Only when this type of information has been determined can a treatment program be refined to maximize its effectiveness while minimizing or eliminating unnecessary features.

Of the studies reviewed, 39% did include some systematic examination of the contributions of different treatment components, although their manipulations were by no means exhaustive. Two studies (Ayllon et al., 1975; Bailey, et al., 1970) investigated the effects of contingent and noncontingent reports home. In the noncontingent condition, the students received "good" reports and subsequent home-based rewards regardless of their school behavior. No treatment effects were observed until a good report was made contingent on actual school behavior. It appears that contingent consequences for target behaviors are necessary for change in

Table 1
Summary of Studies That Used Home-Based Reinforcement Programs to Modify Classroom Behaviors

Author	Experiment	N	Grade	Classroom setting	Target behavior	Adequate design	Systematic variation of treatment	Multiple-outcome measures	Follow-up	School program monitored	Home program monitored

Criterion met[c]						63.0%	38.7%	29.0%	16.1%	38.7%	0%

[a] This study was confounded by multiple interventions. However, the primary purpose of the study was not to examine the effects of home-based reinforcement; therefore, the study was not considered in the adequate design category.
[b] Some of information presented for the Todd et al. study is based on Bostow (Note 3).
[c] Percentage of the number of experiments that met the criterion in each methodological category.

those behaviors. Two other studies (Hawkins et al., 1972; Karraker, 1972) examined a somewhat similar variable, feedback versus feedback plus home-based consequences. Teacher feedback to the child and his/her parents concerning the child's school behavior was not effective unless the feedback was linked with consequences at home. Other treatment components that have been studied are schedule of report home (Saudargas et al., 1977), types of home-based consequences (Schumaker et al., 1977), and types of behaviors targeted for treatment (Kirigin et al., Note 1).

Multiple-Outcome Measures

Another criterion deemed necessary to evaluate treatment effectiveness is the inclusion of multiple-outcome measures. Different outcome measures frequently lead to different conclusions (Forehand & Atkeson, 1977). To provide a complete evaluation of the effectiveness of a home-based program, one should not only measure changes in a child's behavior (e.g., attending to teacher's presentation, talking without permission) and his or her output (e.g., assignment completion, grades) but should also measure changes in the teacher's and parents' perceptions of the child. Therefore, dependent measures that adequately assess the multiple outcomes of treatment (e.g., child behavior change, adult perception change) are required.

Only 29% of the studies reviewed included more than one assessment measure to evaluate their treatment program. Of these studies, only two evaluated the program's effect on the teacher's (Schumaker et al., 1977) or the parents' (Lahey et al., 1977) perception of the child. The remaining studies that used multiple-outcome measures limited their assessment of treatment effect to two measures of the child: (a) changes in the child's classroom behavior and (b) changes in her or his academic output.

Follow-Up

The fourth methodological criterion is the inclusion of follow-up measures to determine the temporal generality of home-based reinforcement programs on school behavior. Even if a treatment program can produce immediate changes in the targeted behaviors, it is of little benefit if these effects are transitory or if they reverse once treatment is terminated. Only 16% of the studies reviewed included follow-up measures to evaluate the long-term effectiveness of their programs. When included, these measures were frequently not rigorous enough to adequately assess temporal generality. For example, some studies examined treatment effects following termination but presented no data (e.g., Strober & Bellack, 1975), and when follow-up data were presented, the measures that were used often were not the same as those used during treatment (e.g., McKenzie et al., 1968). More data are needed before we conclude that home-based reinforcement programs produce lasting effects. In addition, treatment variables that might enhance temporal generality (e.g., fading of treatment) need to be systematically examined.

School Program Monitored and Home Program Monitored

The last two methodological criteria involve treatment implementation. A prerequisite for the evaluation of the effectiveness of treatment is the determination of whether the program was in fact implemented as planned. Home-based reinforcement for school behavior involves treatment implementation in both the school and home; therefore, the behaviors of the change agents in both these settings should be monitored to determine if they are conforming to the program outlined. This evaluation can take several forms. In some studies, the researchers maintained telephone contact with the parents (e.g., Ayllon et al., 1975), others had periodic conferences (e.g., Cohen et al., 1971; Heaton et al., 1976; Kroth et al., 1970; McKenzie et al., 1968), and several placed trained observers in the treatment setting (e.g., Bailey et al., 1970; Lahey et al., 1977; Saudargas et al., 1977). For purposes of methodological evaluation, we selected the last, stricter criterion (i.e., use of observers) as necessary to monitor treatment implementation adequately.

In the school setting 39% of the studies reviewed had observers present. In contrast, none of the studies reviewed monitored treatment implementation in the home with observational data. This lack of control makes it difficult to infer conclusively that the behavioral changes observed in the classroom were in fact due to the treatment and not to other factors in the home. Although this omission in experimental design probably arises from the many difficulties associated with placing trained observers in the home, researchers cannot ignore the necessity for some type of assessment of program implementation in this setting. One solution to this dilemma is currently being examined by Bostow (Note 3). In his study, parents are instructed to audiotape the parent–child interaction when the child receives her/his home consequences that are based on the teacher communication.

Conclusions

The need to involve parents in the school-related problems of their children is evident. Parents are reported to be experiencing a loss of influence over their children as schools are assuming roles once reserved for parents (Woodward, 1978). Home-based reinforcement offers one way in which parents can be incorporated into programs designed to manage the school difficulties of their children. The procedure permits parents to receive regular feedback concerning their child's school behavior. Furthermore, home-based reinforcement encourages frequent teacher–parent communication. From the school's perspective, home-based reinforcement eliminates many of the ethical issues associated with school behavior modification programs, since neither disciplinary procedures nor tangible positive reinforcement have to be used in the school. Furthermore, the procedure circumvents the time-consuming and difficult process of setting up a behavioral classroom program.

In all of the studies reviewed, the conclusion reached by the respective authors was that home-based reinforcement was effective in changing classroom behavior. It is encouraging to note that this conclusion was consistent across a wide range of grades, regular and special classrooms, and academic and disruptive behaviors. The replication of the effectiveness of home-based reinforcement across this variety of ages, settings, and behaviors attests to the general impact of the procedure.

Unfortunately, an analysis of the methodology used in the studies that examined home-based reinforcement yields a less positive picture. Appropriate designs have been used in less than two-thirds of the studies. Furthermore, monitoring of the school and home programs has rarely occurred. Behavior modifiers typically have prided themselves in being well grounded in experimental methodology. Indeed, articles and books have been devoted to the topic (e.g., Birnbrauer, Peterson, & Solnick, 1974; Hersen & Barlow, 1976). Unfortunately, in the case of home-based reinforcement programs, the methodology often has been less than adequate. Other aspects of assessment that are receiving increasing emphasis in behavior modification, such as multiple-outcome measures (e.g., Atkeson, & Forehand, 1978; Turkat & Forehand, in press) and follow-up measures (e.g., Forehand & Atkeson, 1977), have been ignored in the home-based reinforcement studies. Obviously, unless adequate methodologies are employed, our conclusions about the effectiveness of home-based reinforcement procedures will be limited.

Sex Roles and Psychotherapy: A Current Appraisal

Bernard E. Whitley, Jr.
University of Pittsburgh

This article reviews the current status of research on the effects of sex role stereotypes on mental health judgments. Studies in this area have addressed three questions: (a) Are there different, sex-role-related standards of mental health for men and women? (b) Do violations of sex role norms result in adverse mental health judgments? (c) Do therapists set sex-role-related goals for their clients? It is concluded that sex role stereotypes are strong mental health cues for nonprofessionals, with violations of sex role norms leading to adverse mental health judgments, but that whereas professionals share the sex role stereotypes of their lay contemporaries, the professionals are unaffected by them in making mental health judgments and in setting therapeutic goals. This discrepancy between stereotypes and behavior may be due to any of three factors: the methodological limitations of the studies, actual differences in mental health between men and women, or normal attitude–behavior discrepancies.

One of the more popular villains in contemporary psychology is the psychotherapist as a covert (if unwitting) agent of social control and the status quo (e.g., Hurvitz, 1973; Leifer, 1970; Szasz, 1961). This thesis has been most vigorously expounded by a number of feminist writers (e.g., American Psychological Association, 1975; Chesler, 1972; De Beauvoir, 1949/1967; Tennov, 1975) who have charged that therapists define mental health in terms of sex role stereotypes and impose those stereotypes on their clients under the guise of therapy, thereby inhibiting rather than facilitating mental health. If true, these charges are indeed serious, for research has shown that overadherence to stereotyped sex roles is associated with psychopathology (e.g., H. Goldberg, 1976; Gove, 1972; Gove & Tudor, 1973) and low self-esteem (e.g., Bem, 1977; Spence, Helmreich, & Stapp, 1975).

These allegations of sex role bias were supported only by intuition and case histories until the publication of a study by Broverman, Broverman, Clarkson, Rosenkrantz, and Vogel (1970). Broverman and her collegues found that psychotherapists shared the sex role stereotypes of their society and that they included those stereotypes as part of their definition of mental health, thus providing some evidence of therapeutic bias. They did not, however, investigate the extent to which this attitudinal bias resulted in discriminatory behavior. Subsequent investigation of such bias and behavior has generally found no such discrimination and casts doubt on the generality of the bias. This article reviews that subsequent research.

Questions

Within this research, three questions have been of special importance: (a) Are there different, sex-role-related standards of mental health for men and women? (b) Do violations of sex role norms result in adverse mental health judgments? (c) Do therapists set sex-role-related goals for their clients? Although this article reviews the current status of research on these questions, it should be noted that this review only considers research on sex roles in mental health judgments, not on simple sex-of-client effects. Research on the latter's relationship to mental health judgments, test-

ing, and treatment has been briefly reviewed by Abramowitz and Dokecki (1977) and Zeldow (1978).

Subject Populations

Researchers have used three populations of subjects in studying the relationship of sex role stereotypes to mental health judgments: mental health professionals, professional trainees, and nonprofessionals. The first two categories typically include psychiatrists, clinical psychologists, counselors, and social workers. Although most research has been directed at the first two population groups, this review includes research on nonprofessionals as well, both for comparative purposes and because they influence the client referral process (cf. Scott, 1958).

Stereotypes As Standards of Mental Health

Twelve studies have tested the hypothesis that there are different standards of mental health for men and women, which are based on sex role stereotypes (Table 1).[1] Subjects in these studies indicated the chracteristics of the mentally healthy man and woman in one of three ways: by giving a free response, by marking a trait checklist, or by rating the degree to which the stimulus persons possess certain traits (continuous scale). Generally, these studies have tended to support the hypothesis, but many contain flaws that limit their validity.

Results for Different Subject Populations

Mental Health Professionals

The Broverman et al. study. The first, and most cited, study linking sex role stereotypes to mental health standards was that conducted

[1] Not included in this review is a study by Shapiro (1977) that used subjects from a population that the author described as potentially biased.

by Broverman et al. (1970). The psychiatrists, psychologists, and social workers who participated in the study responded to a modified version of a sex role stereotype questionnaire developed by Rosenkrantz, Vogel, Bee, Broverman, and Broverman (1968). The modified questionnaire consisted of 122 bipolar adjective pairs, of which 27 had been determined to be stereotypically masculine and 11 to be stereotypically feminine. Subjects completed the questionnaire by indicating "the pole to which a mature, healthy, socially competent" adult, man, or woman would be closer (Broverman et al., 1970, p. 2). Masculine and feminine health scores were computed relative to the traits assigned to the adult, and significant differences were found between the mean male and female health scores.

Replications of the Broverman et al. study. Fabrikant (1974) and his collegues (Fabrikant, Landau, & Rollenhagen, 1973) attempted to replicate the Broverman et al. (1970) study using an independently developed checklist and free-response items. These studies found sex-role-related mental health standards on the checklist but not on the free-response items.

The results of studies that used continuous scales are mixed. Although Anderson (1975) and Johnson (1974) found stereotyped mental health standards using the Broverman et al. (1970) sex role questionnaire (BSRQ), as did Aslin (1977) for male therapists rating women, Maxfield (1976) did not.

Professional Trainees

Attempts to identify stereotypic mental health conceptualizations among professional trainees have also met with mixed results. Terrill (1972) elicited such stereotypes using a continuous-scale BSRQ with counselor trainees, but Maslin and Davis (1975) and Harris and Lucas (1976) found few such stereotypes with counselor and social work trainees, respectively. Their only statistically significant difference was between male conceptualizations of females and the other subject-stimulus combinations.

Other Subject Populations

Nowacki and Poe (1973) investigated the mental health concepts of college students using a continuous-scale BSRQ. Differences were found for the concepts of mentally healthy man and woman; differences among male subjects were more extreme. Kravetz (1976) employed a continuous-scale BSRQ with a sample of college women. No differences were found between the concepts of mentally healthy man and woman on 73% of the "stereotypic" items, nor were there overall differences. Self-reported membership of some of the subjects in the women's liberation movement had no effect on the results.

Moderating Variables

Variables that have been postulated to interact with the sex of the target to produce stereotyping of mental health concepts include the judge's sex, personal style, and role (therapist vs. nontherapist).

Sex of Judge

As noted above, several studies have found sex of subject effects in conceptualizations of mental health (Aslin, 1977; Harris & Lucas, 1976; Maslin & Davis, 1975; Nowacki & Poe, 1973; also Delk & Ryan, 1977). The usual result is that men tend to stereotype to a greater degree than do women, particularly when men rate women.

Personal Style

A–B therapist status. Delk and Ryan (1975, 1977) have also studied the effects of A–B status on stereotyping. Among therapists, As are more successful at treating schizophrenics, Bs are more successful at treating neurotics, and As tend to attribute more feminine characteristics to themselves than do Bs (Delk & Ryan, 1977). The studies found that As also tend to stereotype more than do Bs.

Personal stereotypes. Comparing therapists' personal sex role stereotypes with the cultural stereotypes, Billingsley (Note 1) found four types of therapists: (a) those whose personal stereotypes accurately reflected the cultural stereotype but included a large number of other beliefs, (b) those whose personal stereotypes were largely inaccurate compared to the cultural stereotypes and included a moderate

number of other items, (c) those who had a moderately accurate personal stereotype and included a moderate number of other items, and (d) those who had an inaccurate personal stereotype with few outside items. Of the four groups, the third differentiated more between mentally healthy men and women, as measured by a continuous-scale BSRQ, than did the other three groups. However, the significance of the differences was not reported.

Subject Population

Delk and Ryan (1977) found that mental patients tended to differentiate between the traits assigned to mentally healthy men and women more than did students, who did so to a greater extent than did therapists. The difference between the patient group and the others may have been due to education as well as patient status, since they were mostly from the lower and lower-middle socioeconomic classes.

Methodological Limitations

Although these studies generally support the hypothesis that there are different standards of mental health for men and women, they have a number of methodological flaws that limit their validity. These limitations can be classified as those concerned with the measurement of stereotypes and those concerned with the scoring of the stereotype measures.

Measurement of Sex Role Stereotypes

The goal of stereotype measurement is to determine the "set of beliefs a person holds about most members of a particular social group" (Oskamp, 1977, p. 124). This task presents two problems: whether the beliefs should be assessed with a free-response or forced-choice format and whether the important beliefs are those about specific behaviors or more generalized personality traits.

Free response versus forced choice. In the free-response situation, subjects describe the mentally healthy man or woman using their own words, whereas in the forced-choice situation, they describe the mentally healthy man or woman using a list of traits provided for them, some of which are sex role stereotypic. The forced-choice response format maximizes stereotypic responses, since the subjects are allowed to respond only with the items listed on the questionnaire, regardless of whether they would ordinarily use them (cf. Lunneborg, 1970). Frieze (Note 2), for example, found that college men and women both gave primarily nonstereotypic responses to stimuli such as "I believe that most women . . .." This phenomenon was also described by Fabrikant (1974; Fabrikant et al., 1973), who found less stereotyping by therapists with free-response items than with an adjective checklist.

Behaviors and traits. The phrasing of the items on a stereotype questionnaire as either specific behaviors or general traits can affect stereotype measurements. Komarovsky (1976) and Steinman and Fox (1966) found that male college students expressed generally nonstereotypic views of women on trait-rating scales but gave more traditional responses when questioned about specific aspects of the female role, such as marriage, motherhood, and work outside the home. Thus the use of trait scales could reduce measured stereotyping.

Use of the BSRQ. Overreliance on the BSRQ itself is a major limitation of the studies described. As a forced-choice measure, the BSRQ has aspects that both increase (the forced-choice format) and decrease (use of traits) stereotyping. Without direct comparison with other instruments, the interpretation of results from the BSRQ is problematical.

Although the BSRQ was used in 10 of the 12 studies reviewed, it hardly represents a consensual definition of sex roles. Sex role inventories have also been developed by Bem (1974) and Spence et al. (1975), and the three questionnaires contain a total of 42 feminine and 53 masculine traits, of which only 2 feminine and 7 masculine traits are common to all three. In addition, only the Bem questionnaire has its masculine and feminine items matched for social desirability and has been validated against behavioral criteria (Bem, 1974, 1977). The results of a study that uses the Bem (1974), Spence et al. (1975), or a combined questionnaire could be different from one using the BSRQ.

Scoring the Stereotype Measures

Forced-choice questionnaires can be scored on either a dichotomous or a continuous scale. Using a dichotomous scale, subjects can report whether they think a trait is characteristic of a man or a woman but not the degree to which it is characteristic. This scoring system was used in the Broverman et al. (1970) and adjective checklist portions of the Fabrikant (1974; Fabrikant et al., 1973) studies. This procedure tends to inflate the extremity of scores by eliminating the possibility of a qualified or neutral rating. Investigating the implications of a dichotomous versus a continuous scale, Maxfield (1976) found a marked reduction in the rating of male–female differences when they were measured on a continuous-scale version of the BSRQ, with no statistical difference on 59% of the stereotypic items. It would thus appear that the Broverman et al. (1970) and Fabrikant (1974; Fabrikant et al., 1973) checklist findings should be interpreted with a great deal of caution.

Even when continuous scales are used, there are problems of interpretation, since most sex differences found on individual items of mental health questionnaires are of degree rather than kind (e.g., Johnson, 1974; Kravetz, 1976; Maslin & Davis, 1975; Maxfield, 1976). That is, given a bipolar adjective continuum, men and women are usually rated on the same side of the neutral point. Although the pictures of the mentally healthy man and woman may differ statistically under these conditions, the conceptual differences to the respondant may not be so great.

Summary

Although the findings of the studies that tested the hypothesis that there are different, sex-role-related standards of mental health for men and women are generally positive, methodological shortcomings cast doubt on their validity. At best, it çan be said that when equivalent measures are used, mental health professionals share the sex role stereotypes of their lay contemporaries.

Effect of Violations of Sex Role Norms on Judgments of Mental Health

If the hypothesis that there are different, sex-role-related standards of mental health for men and women is accepted, then a second hypothesis follows: The exhibition of cross-sex-role behavior leads to adverse judgments of mental health. This hypothesis has been tested in the 24 studies listed in Table 2. Research in this area has been of two types: analogue studies, in which subjects base their judgments on fictitious cases specially constructed to coincide with the independent variables of the study, and field studies, in which actual therapist–client relationships are examined. Generally, the hypothesis has been supported for nonprofessionals but not for mental health professionals.

Analogue Studies

In analogue studies, subjects are typically presented with a written description of a stimulus person whose sex role orientation is varied between judges. These stimulus persons are then rated on adjustment, mental health, or similar measures. There are three major subcategories of analogue studies: those that use only female stimulus persons, those that use both male and female stimulus persons and in which only one or two characteristics are varied to manipulate sex role orientation, and those that use both male and female stimulu s persons and in which several characteristics are varied.

Mental Health Professionals As Subjects

Female stimulus persons only. The four studies that used only female stimulus persons manipulated sex role orientation by varying one trait: Thomas and Stewart (1971), Abramowitz et al. (1975), and Hill, Tanney, Leonard, and Reiss (1977) used career choice as the critical trait, whereas Abramowitz, Abramowitz, Jackson, and Gomes (1973) used political activism. The results of these studies were generally negative, with the exception that Abramowitz et al. (1973; Abramowitz et al., 1975) found that subjects with more traditional attitudes tended to rate nontraditional stimulus persons lower on adjustment than did less traditional subjects.

Male and female stimulus persons, single trait. In these studies, sex role orientation of the stimulus persons was manipulated by varying the traits of independence and achievement (Pringle, 1973) and active versus passive

personal style (Chasen, 1975; Chasen & Weinberg, 1975; Fischer, Dulaney, Fazio, Hudak, & Zinotofsky, 1976). None of these studies supported the hypothesis that cross-sex-role behavior leads to adverse judgments of mental health.

Male and female stimulus persons, multiple traits. Once again, the hypothesis was generally not supported (Berland, 1976; Bilick, 1973; Gomes & Abramowitz, 1976; Maxfield, 1976). However, Tribich (1977) found that males who responded to a crisis with crying and other "feminine" reactions were rated as more disturbed than a woman who reacted in the same manner and as more disturbed than either a man or a woman responding with anger and other "masculine" behaviors. In addition, Feinblatt and Gold (1976) found that although graduate students in clinical and school psychology did not rate the severity of a

problem greater in cross-sex-role children, they did make a stronger recommendation for treatment and a bleaker prediction for future adjustment if the behavior continued.

Other Subject Populations

Male and female stimulus persons, single trait. Studies that used college students as subjects found evidence in support of the hypothesis. In two experiments that used the traits active and passive, Costrich, Feinstein, Kidder, Marecek, and Pascale (1975) found that cross-sex-role stimulus persons were rated as being in greater need of therapy than their in-role counterparts, and Derlega and Chaikin (1976) found lower adjustment ratings for violators of self-disclosure norms. In a complex study of variables that affect mental health judgments, Coie, Pennington, and Buckley (1974) found marginally greater ratings of mental disturbance for female stimulus persons who reacted aggressively to stressful situations and for male stimulus persons who reacted to the same situations with somatic complaints.

Male and female stimulus persons, multiple traits. Using college students as subjects, Burhenne (1972) and Israel, Raskin, Libow, and Pravder (1978) found lower mental health ratings for cross-sex-role stimulus persons. Zeldow (1976), however, found sex role effects only for male subjects rating female stimulus persons. Feinblatt and Gold (1976) had a sample of parents rate the same cases as did the graduate students in another part of their study and found ratings of greater problem severity and less future adjustment for cross-sex-role children. Tribich (1977) also had nonprofessional adults rate the same cases as did his therapist subjects and again found that feminine behaviors in men led to more severe mental health ratings.

Moderating Variables

Sex of judge. Generally speaking, sex of rater has not affected judgments of mental health in relation to violations of sex role norms (Bilick, 1973; Chasen, 1975; Chasen & Weinberg, 1975; Derlega & Chaikin, 1976; Feinblatt & Gold, 1976; Gomes & Abramowitz, 1976; Maxfield, 1976; Tribich, 1977). However, woman therapists tend to be slightly more accepting of counterstereotypic behavior than men (Chasen, 1975; Chasen & Weinberg, 1975) and more lenient in their ratings of all stimulus persons (Abramowitz et al., 1975; Harris & Lucas, 1976; Maxfield, 1976). Israel et al. (1978), however, found female college students to make more severe ratings than male students.

Attitudes. Abramowitz and his collegues (1973; Abramowitz et al., 1975), working with female stimulus persons only, found that counselors with more traditional attitudes tended to attribute less adjustment to women with deviant career goals and political attitudes. Other studies (Chasen, 1975; Gomes & Abramowitz, 1976), however, have failed to replicate the attitude–sex role interaction for stimulus persons with deviant and conforming sex role traits. Although these differences may be due to differences in population (counselors vs. psychologists), the differences in stimulus material are also striking: The counselors in the first studies rated behaviors, whereas the psychologists in the attempted replications rated traits.

Situations. Although Coie et al. (1974) found marginal support for the use of sex role stereotypes in mental health judgments made by college students, they also found that the situations that elicited the judged behaviors and the situation–behavior interaction were more important cues than the stereotyping of the reaction. For example,

> relatively little disorder was attributed for social withdrawal compared to aggression in the context of exam pressure, whereas social withdrawal was seen as evidencing at least as much disorder as aggression in the context of rejection. (p. 563)

This finding suggests that situational context as well as behavioral description may be an important factor in the experimental materials.

Field Studies

Archival Studies

Two of the field studies of sex roles and judgments of mental health are archival. That is, they examined the records of a child guidance clinic (Feinblatt & Gold, 1976) and a university counseling center (Collins &

Sedlacek, 1974) for patterns of referrals related to sex role behavior. It should be noted that these studies examined requests for treatment (made directly by college students or by parents for children), not acceptance for treatment, and thus they reflect nonprofessional judgments of mental health. Collins and Sedlacek's analysis of screening interviews found that male students tended to seek counseling for vocational, educational, and underachievement problems, whereas female students sought counseling for emotional and social conflicts. Feinblatt and Gold found that 33% of the children seen at a guidance center were referred for sex-role-related behaviors and that 89% of these were for cross-sex-role behaviors. Thus failure to meet behavioral sex role expectations may be seen as a mental health problem by nonprofessionals.

Surveys

Cowan (1976) surveyed a sample of primarily male consulting psychologists by having them complete the BSRQ for the typical male and female patient, "indicating the extent to which they think one of the two poles represents the greater problem" (p. 120). She found that female clients were rated as being too feminine—less than optimum on masculine traits and more than the optimum on feminine traits—whereas male clients were not viewed in sex role terms as measured by the BSRQ. A measurement qualification arises from the fact that the psychologists, in response to another question, reported that sex role expectations underlay the problems of their male and female clients to the same extent, a finding that may reflect the inadequacy of the BSRQ as a definition of sex roles.

Interviews

On the other hand, Levy and Doyle (1974) found a slight tendancy for staff members at a drug abuse rehabilitation center to see residents' problems in sex role terms. These data, however, were scored dichotomously and reflect the views of nonprofessionals as well as professional staff, both conditions tending to increase the degree of stereotyping found.

Methodological Limitations

The weight of experimental evidence tends to disconfirm the hypothesis that violations of sex role norms result in adverse mental health judgments made by professionals and to support it for judgments by nonprofessional judges. There are, however, aspects of the stimulus material and dependent variables in the analogue studies that merit a closer look.

Independent Variable Manipulation

Specific sex-role-deviant behaviors seem to lead to more adverse judgments than trait lists. For example, Abramowitz et al. (1973; Abramowitz et al., 1975) found an interaction between counselor attitudes and stimulus behavior that led to lower adjustment ratings, whereas studies that used traits did not (Chasen, 1975; Gomes & Abramowitz, 1976). With nonprofessional subjects, Derlega and Chaikin (1976) found a much stronger effect using a specific behavior than did the other investigators who used traits. In cases such as these, behavioral description may add realism and dimension to the experimental situation. For example, the trait *very aggressive* is vague, covering a wide variety of behaviors, whereas the description "Joe pushed Tom down a flight of stairs" gives a more precise measure of aggression and allows the rater to judge the appropriateness of the response to the situation (cf. Coie et al., 1974). Degree and appropriateness of behavior are probably more salient mental health cues than traits and should be used more often in mental health studies.

Dependent Measures

Feinblatt and Gold (1976) found that clinical and school psychology graduate students rated children showing in- and cross-sex-role behavior about neutral in respect to severity of problem but that they recommended treatment more urgently and predicted less future adjustment for the cross-sex-role children. It would thus appear that ratings of present mental health, need for treatment, and future mental health elicit different judgments. It is reasonable to decide that a person is relatively healthy now but may get worse

and so needs treatment. This situation suggests the need for multivariate dependent measures of mental health that assess present perceptions and future expectations.

Summary

Mental health professionals are relatively uninfluenced by violations of sex role expectations in making mental health judgments. On the other hand, nonprofessional judges are affected by such violations when making similar decisions. These therapist–lay differences may be due to the fact that therapists stereotype to a lesser degree than do other groups (Delk & Ryan, 1977) or to the fact that the most common nontherapist subject population consists of college students. The latter explanation is supported by Tribich's (1977) finding of minimal sex role bias in the mental health judgments of either therapists or adult white-collar workers. It is also possible that the source of the differences lies in the experimental procedures and that the use of behavioral rather than trait descriptions and the use of multivariate dependent measures could affect the findings among clinicians.

Treatment Goals

Five studies have investigated the hypothesis that treatment goals tend to be sex role related (Table 3). These studies have generally failed to support this contention, although some specific goals may be sex typed.

Analogue Studies

Billingsley (1977) and B. J. Goldberg (1976) compared the treatment goals set for clients who varied in sex and problem. Neither study found stereotyped goals. Rather, the masculinity or femininity of goals depended on the type of problem: more feminine goals were recommended for potentially violent clients regardless of sex, and more masculine goals were recommended for withdrawn clients (Billingsley, 1977). Such goals suggest that the ideal person may be seen as a mixture of the masculine and feminine and that both extremes are undesirable.

Table 3
Studies That Investigated Therapy Goals

Field studies	
Fabrikant (1974)	−
Levy & Doyle (1974)	+

Note. + = supports hypothesis; − = does not support hypothesis.

Investigating counselor reactions to high and low dependence and achievement in male and female clients, Pringle (1973) found that both male and female counselors expressed a greater desire to change the behavior of low-achieving male clients than that of low-achieving female clients. In addition, male counselors recommended less change for dependent women and all high achievers than did female counselors.

Field Studies

Fabrikant (1974) surveyed patients in psychotherapy about their perceptions of their therapists' sex role goals for them. Only perceptions of male therapists were reported, and these perceptions generally failed to support the hypothesis of sex-role-related treatment goals. A sizeable minority (27%) of female patients, however, endorsed the statement that "male therapists encourage female patients to follow the role of wife/mother" (p. 101). On the other hand, they were not asked if their therapists discouraged such traits as independence and assertiveness.

Reporting on a drug rehabilitation program, Levy and Doyle (1974) state that "a stable relationship with a member of the opposite sex is important for a woman to complete the program while more credence is given to a male's realistic job plans" (p. 430). They neglect, however, to present any data relevant to the degree of importance of these two factors in making rehabilitation judgments, so no firm conclusions can be drawn.

Summary

Relatively little research has been conducted investigating treatment goals as a function of sex role stereotypes, and that tends to be generally negative. There are indications, however, that reactions to some specific behaviors (Pringle, 1973) and that some specific goals (Fabrikant, 1974) may be sex typed. This would still appear to be a fertile area for investigation.

Although adherence to a stereotype is generally not used as a treatment goal, it is possible that therapist-encouraged sex roles may have beneficial effects on some clients. Delk and Ryan (1977) note, for example, that Type A therapists, who stereotype the most, are also the most successful with schizophrenics. They suggest that these therapists provide structure and a "definitive role model of culturally valued and socially acceptable behavior" (p. 258) for a patient group characterized by ambivalence, confusion, and need for structure.

Conclusions

Nonprofessionals

Sex role stereotypes appear to be strong mental health cues for nonprofessionals. They hold stereotypic standards of mental health, and cross-sex-role traits and behaviors are seen as indicators of poor mental health and adjustment. When nonprofessionals evaluate reactions to stressful situations, however, it would appear that the situational context is a more important mental health cue than the reaction's sex role appropriateness.

Mental Health Professionals

Although the evidence concerning differential mental health standards for men and women indicates that clinicians share the sex role stereotypes of their lay contemporaries, there is little evidence that these stereotypes affect professional judgments or treatment goals. Although this apparent contradiction between studies of clinicians' attitudes and their behavior may be primarily due to the methodological limitations of the studies, as suggested by Davidson and Abramowitz (in press), there are two other possible explanations.

First, Gove (in press) has noted that a number of studies have found generally poorer mental health among women than among men, and he has concluded that if these data are accurate, then clinicians' differential mental health ratings of men and women could be more a reflection of reality than of stereotyped attitudes. In such a case one would not expect biased judgments or treatment goals, and the contradiction between the two sets of studies disappears.

Second, even given stereotyped attitudes, a contradiction does not necessarily arise. Social psychologists have long known that people's behavior relative to an object has little relationship to their attitudes toward the object. Fishbein and Ajzen (1975) suggest that a person's attitude toward a possible behavior directed at an object and the social norms that constrain that behavior determine the behavior more powerfully than does the person's attitude toward the object alone. Thus therapists' judgments of mental health and therapeutic goals may be more strongly determined by their attitude toward, and the norms surrounding, the imposition of traditional sex roles than by their sex role stereotypes alone. In the area of attitudes about specific behaviors, Fabrikant (1974) found that therapists valued the client's personal growth over traditional role enactment. This behavioral attitude is congruent with current therapeutic norms that stress the development and expression of the client's personal values, talents, and autonomy rather than passive social adjustment (cf. Corey, 1977; Orne, 1975). These norms have been emphasized especially strongly relative to woman clients (e.g., American Psychological Association, 1975; Rawlings & Carter, 1977). Under such conditions, sex role stereotypes may have little effect on therapist behavior.

The apparent exception to this rule concerns children. As previously noted, Feinblatt and Gold (1976) found that although therapist trainees were somewhat accepting of cross-sex-role behavior in children, they see a bleak future for them. This may reflect concern that the behaviors could lead to later homosexu-

ality, transsexuality, or social rejection (cf. Green, 1974; Rekers, Rosen, Lovaas, & Bentler, 1978).

Thus the influence of sex roles on psychotherapy appears to be more limited than some critics charge. This does not mean that the critics are necessarily wrong; it is more likely that therapists' attitudes have changed. Indeed, until recently, sex role congruence and mental health have been closely identified in the professional literature (e.g., Garai, 1970; Hurlock, 1974), and the change from this position may be attributable to the success of the women's movement in raising the consciousness of the psychotherapeutic establishment.

Application of Biofeedback for the Regulation of Pain: A Critical Review

Dennis C. Turk
Yale University

Donald H. Meichenbaum
University of Waterloo, Ontario, Canada

William H. Berman
Yale University

The biofeedback literature for the regulation of pain is reviewed and found wanting on both conceptual and methodological grounds. In particular, studies on the use of biofeedback for the treatment of tension and migraine headaches and chronic pain indicate that biofeedback was not found to be superior to less expensive, less instrument-oriented treatments such as relaxation and coping skills training. The relative absence of needed control comparisons was noted, and the need for caution in promoting biofeedback was stressed. Suggestions for future research are offered.

During the past 10 years, there has been a proliferation of journal articles, books, research centers, workshops, and training programs devoted to biofeedback and the regulation of pain. The plethora of advertisements for biofeedback devices in medical and psychological magazines attests to the increasing popularity of these techniques as clinical tools. Perhaps the most telling evidence for the widespread popularity of this technique is the amount of coverage it has received in the media. In short, extraordinary public and professional attention has been given to the topic of biofeedback, often with spectacular claims made for the efficacy of these procedures for pain control. An examination of the research reveals a number of discrepancies and methodological problems that bring such glowing evaluations into question.

The purpose of the present article is to examine the empirical evidence that supports the relative efficacy of biofeedback techniques for the control of various pain syndromes. Because of the amount of data on this topic, the objective of this article is to provide a comprehensive rather than exhaustive coverage of the literature.

Requests for reprints should be sent to Dennis C. Turk, Department of Psychology, Box 11A Yale Station, Yale University, New Haven, Connecticut 06520.

What Is Biofeedback?

Biofeedback encompasses a wide variety of techniques that use biophysiological instrumentation to provide patients with information about changes in bodily functioning of which the person is usually unaware. The biofeedback training paradigm in general follows an operant learning framework. First, some body function that is to be brought under control is identified and assessed to provide a baseline of moment-to-moment changes. These changes are quantified and translated into information that is immediately fed back to the subject in the form of visual signals or auditory tones. The information regarding fluctuations in physiological activity provides subjects with data concerning the efficacy of their attempts to influence the specific physiological response. By trial and error the subject learns to recognize the subjective state and subtle internal changes associated with an alteration of physiological activity. As the subject becomes more proficient at controlling the signal, instrument sensitivity is adjusted to permit gradual shaping of the physiological response.

The physiological activity to be controlled varies as a function of the etiology of the symptoms to be regulated. Put simply, the intent of the biofeedback is to provide patients with information that will in turn enable

them to *voluntarily control* some aspect of their physiology that purportedly is causally linked to the pain experienced.

A number of important assumptions underlie the clinical use of biofeedback. One assumption is that the etiological variables and the pathophysiology of the pain to be controlled are known and can be subjected to voluntary control. A second assumption is that learned control of a bodily response is facilitated by information about activity in the relevant organ system. A third assumption is that through the biofeedback training, the patient will be able to recognize some of the situational factors that are related to the maladaptive physiological responding. A final assumption is that the skills learned during the biofeedback training will generalize to situations in the patient's natural environment, and as a result, these skills will be maintained over time and settings. That is, the patient will be able to engage in conscious control of relevant physiological responses outside the clinic or laboratory setting. Since most of the biofeedback training studies concerned with pain regulation have used patients with headaches (tension, migraine), this review first examines this literature and then examines other clinical pain populations.

Muscle Contraction Headache

The exact etiology of muscle contraction headache is unclear (Bakal, 1975). There is, however, a consensus that muscle contraction headaches (a) are an individual's response to psychological stress (American Medical Association, 1962; Dalessio, 1972; Martin, 1966) and (b) may result from excessive and sustained contraction of the frontalis (forehead), scalp, or neck muscles (Bakal, 1975; Martin, 1972). The traditional treatment of muscle contraction headaches usually entails symptomatic medication, for example, tranquilizers, muscles relaxants, or analgesics, and occasionally psychotherapy.

In 1954 Sainsbury and Gibson reported that the resting levels of frontalis electromyographic (EMG) activity were higher in patients with muscle contraction headaches than in normals. In 1969 Budzynski and Stoyva also demonstrated an association between frontalis EMG activity and tension in varying scalp and neck muscles. This association provided the basis for Budzynski, Stoyva, and Adler's (1970) suggestion that biofeedback would facilitate a patient's ability to attain "deep levels of relaxation" (p. 206) and would subsequently enable the client to "consciously control muscular tension" (p. 206). This led to a series of biofeedback studies (Budzynski et al., 1970; Budzynski, Stoyva, Adler, & Mullaney, 1973) in which tension headache patients were given frontalis EMG feedback.

In their initial report, Budzynski et al. (1970) provided five muscle contraction headache patients with frontalis EMG biofeedback training. Surface electrodes attached to the forehead provided information that was fed back by way of a tone, with the frequency of the tone proportional to the integrated EMG activity. Patients were instructed to attempt to keep the tone at the lowest frequency possible and were not provided with instructions as to how this might be accomplished. In addition, the patients were instructed to practice at home twice a day the skills that they had acquired during the feedback training. The amount of training received by the patients varied from 4 to 13 weeks, with two 30-minute sessions each week.

Budzynski et al. (1970) reported a steady decline in headache intensity and duration and EMG activity over the course of the training. A follow-up was conducted 3 months after the conclusion of the training. Muscle contraction headaches were eliminated in two patients and were reduced markedly in a third. For the remaining two patients, headaches returned shortly after the end of the feedback training.

Although the Budzynski et al. (1970) study demonstrates that patients can learn to reduce headache intensity as well as frontalis EMG activity, the effects cannot necessarily be concluded to be a direct result of the EMG feedback training. Because of the preliminary nature of the investigation, Budzynski et al. did not include any group to control for placebo or expectancy effects. Without such controls it is impossible to separate any active effect of the EMG training from nonspecific treatment effects associated with the

impressive biofeedback "ritual" (Miller, 1974; Shapiro & Surwit, 1976). Since the biofeedback treatment in Budzynski et al.'s study involved such components as EMG training, home practice, expectancy of alleviation of headaches, self-monitoring of stress-inducing situation, and a format that engendered a sense of control (cf. Epstein & Blanchard, 1977; Glass & Levy, in press), it is difficult to attribute improvement to the EMG feedback component. Another limitation of the Budzynski et al. study is the use of only a 3-month follow-up, since spontaneous fluctuations of headache incidence have been noted (Ostfeld, 1961). Given all of these shortcomings, the Budzynski et al. study provided impetus for further research.

In a better controlled study of biofeedback for the control of muscle contraction headache, Budzynski et al. (1973) compared the efficacy of frontalis EMG biofeedback, self-monitoring of headache intensity and duration with no feedback, and a noncontingent yoked feedback group. (The feedback signals were those produced by the true feedback group and were unrelated to any behavior on the part of the patients in this group.) Patients in the EMG and false feedback groups received 16 30-minute sessions of biofeedback training. The patients in both groups were instructed to practice at home twice a day the skills that they acquired during training.

At the end of training and at a 3-month follow-up, patients in the EMG feedback group had significantly reduced the intensity and duration of headache and frontalis muscle activity from the baseline period, whereas the self-monitoring and false feedback groups demonstrated no significant improvement. Interestingly, two patients in the biofeedback group who did not show significant reductions in headache intensity or duration both reported that they did not carry out the home practice, suggesting the potential importance of home practice in the biofeedback regimen.

Budzynski et al. (1973) contacted four of the six patients in the EMG feedback group 18 months after the completion of training. Three of the four patients reported that their headaches remained at very low levels with the fourth subject indicating that she had received some relief from headache activity following the training. This maintenance of improvement over such an extended period is impressive. Since the patients in the false-feedback and no-feedback groups were provided with true EMG feedback training after the 3-month follow-up, it is impossible to determine whether the continued improvement of the biofeedback group was a function of the training or of spontaneous fluctuations of headache incidence. Budzynski et al. did not provide any information as to whether the biofeedback subjects demonstrated reductions in EMG activity at the 18-month follow-up concordant with the reduction in headache incidence.

Although the second Budzynski et al. study (1973) was much better controlled, the design does not permit isolation of the contribution of the various components of the treatment regimen. The relevance of the EMG training to therapeutic gains is somewhat obscured by the instructions provided to the patients regarding the need to engage in home practice of skills acquired in the laboratory. The necessity of home practice has been addressed by several authors (e.g., Epstein, Hersen, & Hemphill, 1974; Haynes, Griffin, Mooney, & Parise, 1975; Wickramasekera, 1972), but its importance to biofeedback treatment is unresolved. Epstein et al. (1974) presented data from a single case study that supported the necessity of including home practice; on the other hand, Wickramasekera (1972) and Haynes et al. (1975) both reported substantial reductions in headache incidence resulting from biofeedback training that did not include suggestions for home practice.

All of the studies reviewed so far provide at least presumptive evidence that frontalis EMG biofeedback can reduce muscle contraction headache incidence. An important issue, however, is how useful biofeedback is in comparison to other less expensive approaches that are designed to regulate headache incidence. For example, several investigators (Epstein, Webster, & Abel, 1976; Fichtler & Zimmermann, 1973; Tasto & Hinkle, 1973) have reported that relaxation training without biofeedback training was sufficient to significantly reduce muscle contraction headaches. Another approach to alleviate muscle contraction headaches has

recently been used successfully by Holroyd, Andrasik, and Westbrook (1977). The therapeutic regimen used by Holroyd et al. was designed to train patients in a number of stress-coping skills to enable them to cope more adaptively with environmental and individual stylistic responses that instigated muscular tension. Further research should determine whether biofeedback techniques, which require sophisticated and expensive psychophysiological apparatus, are any more efficient or effective than more readily available and less expensive interventions.

Several recent studies (Chesney & Shelton, 1976; Cox, Freundlich, & Meyer, 1975; Haynes et al., 1975; Hutchings & Reinking, 1976; Holroyd et al., 1977) have addressed this issue by comparing the efficacy of frontalis EMG biofeedback with relaxation training or stress coping training. The data reported is equivocal but does not in general support the contention that biofeedback training is any more effective than various relaxation or cognitive control techniques.

In the Hutchings and Reinking (1976) study, three groups received EMG biofeedback training alone, relaxation training alone, or a combination of biofeedback plus relaxation training. All three groups were instructed to practice at home twice daily the skills that they had acquired. The groups who received the EMG training demonstrated significant reduction in headaches during a 28-day follow-up period compared to the relaxation training group. The EMG feedback and combined EMG feedback plus relaxation groups did not differ significantly in the incidence of headaches following training. Although patients in all three groups revealed reductions in frontalis muscle action potential following treatment, no significant between group differences were obtained, and no correlational data were reported between the amount of reduction in headache activity and the degree of EMG reduction. These data do suggest that biofeedback training is more effective than relaxation training; however, they also question the significance of frontalis EMG control for the reduction of muscle contraction headache.

Studies by Cox et al. (1975), Haynes et al. (1975), and Chesney and Shelton (1976) provide evidence that contradicts the Hutchings and Reinking (1976) findings. Although Cox et al. and Haynes et al. both report that EMG biofeedback was effective in alleviating headaches, groups who received the EMG training did not differ significantly from groups who received relaxation training. In the Chesney and Shelton (1976) study, only the relaxation training group demonstrated significant reductions in headache incidence, the EMG biofeedback group reduced headache incidence no more than a no-treatment control group.

In a recent study, Holroyd et al. (1977) used a therapeutic intervention that focused on altering maladaptive cognitive responses that were assumed to mediate the occurrence of muscle contraction headaches. Patients were provided with a rationale for treatment, which emphasized the function of specifiable maladaptive cognitions in the creation of subsequent disturbing emotional and behavioral responses (based on Beck, 1976 and Meichenbaum, 1977). Patients were encouraged to attribute their headaches to relatively specific cognitive self-statements rather than to situational or complex internal dispositions. A variety of stressful situations were identified, and patients were taught to focus (a) on the situational cues that trigger tension and anxiety for them, (b) on their response to these cues, (c) on their thoughts before becoming tense and after the development of tension, and (d) on the way in which these cognitions contributed to the tension headaches. Following this sequence, patients were instructed to deliberately interrupt the sequence of thoughts preceding their emotional response at the earliest possible point and to engage in cognitive control techniques incompatible with further stress and tension (e.g., cognitive reappraisal, attention deployment, fantasy).

This cognitive control regimen was employed with 10 tension headache patients who were compared to patients who received either biofeedback or no specific treatment. Training consisted of 8 biweekly sessions with a 15-week follow-up. At the termination of treatment and at follow-up, only the cognitive control group demonstrated substantial improvement on frequency, duration, and in-

tensity of headaches. Interestingly, only the biofeedback group demonstrated significant reductions in EMG activity. This latter finding raises the question of the assumed causal relationship between frontalis EMG activity and muscle contraction headaches.

Hutchings and Reinking (1976) also questioned the contribution of frontalis muscle tension in the development of muscle contraction headaches. The questionable relationship between EMG activity and experience of tension headaches is underscored further by Holroyd et al.'s (1977) data and the observation made by Haynes et al. (1975) that several of the patients in their study did not demonstrate a significant relationship between headache occurrence and EMG activity. Simply put, some individuals with extremely high frontalis EMG levels reported few or no muscle contraction headaches. Others with relatively low frontalis EMG reported frequent muscle contraction headaches.

Several recent studies have corroborated the independence between headache incidence and elevated EMG levels (Alexander, 1975; Cox et al., 1975; Coursey, 1975; Epstein & Abel, 1977; Holroyd et al., 1977). These recent findings are inconsistent with the significant relationship between headache incidence and EMG level ($r = .90$) reported by Budzynski et al. (1973). Cox et al. suggest that the discrepancies in the various studies may be accounted for by the sampling procedures of the EMG activity. Budzynski et al. (1973) recorded EMG levels during feedback sessions, whereas Cox et al. took EMG readings during pre- and posttreatment baseline sessions. But several other studies (Epstein & Abel, 1977; Haynes et al., 1975; Holroyd et al., 1977) that have sampled frontalis EMG levels in a method analogous to that of Budzynski et al. have not found a significant relationship between frontalis EMG and headache incidence, thus questioning Cox et al.'s explanation.

Other interpretations are possible. First, the etiology of muscle contraction headache may not result in high levels of frontalis EMG activity but rather in muscle contraction in other parts of the head, neck, and shoulders, with little generalization across the various muscle groups (Haynes et al., 1975). Second, changing frontalis muscle activity may not be sufficient for changes in self-report of headaches (Epstein et al., 1976; Holroyd et al., 1977). Third, the relationship between muscle contraction and muscle contraction headaches may not be isomorphic or unidimensional (Bakal, 1975). And finally, muscle tension changes may not always serve as the cue for reporting headaches (Epstein & Blanchard, 1977; Holroyd et al., 1977). In any case the evidence does not convincingly demonstrate that frontalis EMG reduction and self-report of tension headaches are concordant. Thus it seems premature to conclude that the positive effects of biofeedback approaches, when indeed they occur, are a function of increasingly voluntary control of frontalis muscle activity.

Table 1, which contains a summary of the studies that examined the relative efficacy of biofeedback in controlling muscle contraction headaches, places the biofeedback treatment procedure in some perspective. Perusal of Table 1 reveals that the majority of studies agree that frontalis EMG biofeedback is effective in the reduction of headache incidence, but when contrasted with alternative therapeutic interventions and no-treatment controls, these results are less impressive. In four out of seven studies, biofeedback training is no more effective than other approaches (e.g., relaxation, stress coping training) or no-treatment control groups. In addition, only four of nine studies reported any concordance between reductions in EMG levels and headache incidence.

Although the data are not conclusive, from a clinical perspective it appears that a number of psychologically oriented treatments (i.e., relaxation, biofeedback, cognitive control techniques) can be successfully used to ameliorate chronic muscle contraction headaches. It is thus unclear whether EMG biofeedback is more effective in relieving muscle tension than are other methods of relaxation, nor is it clear how patients use the skills acquired during training. Interviews with patients who have received biofeedback training reveal that they often generate cognitive instructions to themselves about what might relax them and then try out the approaches, using EMG feedback as a criterion (Hutchings & Reinking,

Table 1
Summary of Studies That Examined the Efficacy of Biofeedback in Regulating Muscle Contraction Headaches

Effect of frontalis EMG on headache activity			Comparison of effects of frontalis EMG activity and comparison groups[a]			Concordance between physiological activity and headache incidence		
Significant reduction	No significant reduction	Equivocal	EMG superior to comparison	EMG equal to comparison	EMG inferior to comparison	Concordant	Discordant	Equivocal
Budzynski, Stoyva, & Adler (1970)	Chesney & Shelton (1976)	Epstein & Abel (1977)	Wickramasekera (1972)[b]	Cox et al. (1975)	Chesney & Shelton (1976)	Budzynski et al. (1970)	Cox et al. (1975)	Hutchings & Reinking (1976)

Cox, Freundlich, & Meyer (1975)								
Haynes, Griffin, Mooney, & Parise (1975)								
Hutchings & Reinking (1976)								

Note. EMG = electromyograph.
[a] All groups other than contingent frontalis EMG biofeedback training are treated as comparison groups. These include relaxation, noncontingent biofeedback, medication, and stress coping training (Holroyd et al., 1977).
[b] No statistical analyses were reported, thus we can only assume that the effects were significant.

1976). If an essential element of biofeedback training is the development of such cognitive and behavioral stratagems, then perhaps a more efficient and less expensive method of achieving relaxation would simply be to instruct patients in various methods of relaxation. The EMG biofeedback could then be used for a brief period to help the patient identify the most effective strategy. As Coursey (1975) asks, "what sort of relaxation technique is effective with what sort of people with what sort of problems in conjunction with what other procedures?" (p. 833).

It is clear that biofeedback training for the control of muscle contraction headaches directly addresses only the maladaptive physiological responses to stressful situations and ignores those psychological factors that initiate and contribute to such responses. As was noted previously, a three-stage process is generally believed to produce muscle contraction headaches: (a) The individual responds to psychological stress, which (b) may produce prolonged contraction of the muscles in the head, neck, or shoulders and which (c) may subsequently lead to the production of headache (American Medical Association, 1962; Bakal, 1975). To successfully treat muscle contraction headaches, a therapeutic regimen that addresses the first stage (response to psychological stress), such as the stress-coping training (Holroyd et al., 1977; Reeves, 1976), should be combined with treatments that focus on the second stage (maladaptive physiological responding). (See Turk & Genest, 1979, for an extensive review of such multifaceted treatment approaches with pain patients.) The failure of biofeedback procedures to specifically address individuals' maladaptive appraisals and behaviors in the natural environment may account for (a) the equivocal data, (b) for the relatively high number of patients who drop out of biofeedback treatment prematurely, as well as (c) the individual differences in the ability to benefit from feedback training (Lazarus, 1977; Meichenbaum, 1977; Turk & Genest, 1979).

In summary, the enthusiasm for the therapeutic application of frontalis EMG biofeedback for the control of muscle contraction headaches exceeds the available evidence of the efficacy of this approach as compared to other psychological approaches. Although biofeedback procedures have been shown to be useful, they should still be considered promissory at best, with many questions remaining unanswered.

Migraine (Vascular) Headache

The existing data on the pathophysiology of migraine headaches is sparse. The available physiological evidence suggests that migraine headache is associated with (a) excessive cranial vasculature responsivity and (b) autonomic nervous system instability (Bakal, 1975). The symptoms of migraine headaches are thought to be mediated through the autonomic nervous system and are often evidenced by increased blood flow in the head, which results in painful dilation and distention of the cranial arteries. A wide range of substances that produce vasoconstriction, including ergotamine tartrate, pituitrin, ephedrine, benzidrine, ephinephrine, and caffeine, have been shown to be more or less effective in relieving migraine, when administered prior to the establishment of edema (Dalessio, 1972).

Sargent, Green, and Walters (1972), who noted the association between migraine headache and cold extremities (Dalessio, 1972), hypothesized that the voluntary increase in finger temperature should be correlated with an increase in blood flow to the peripheral region and consequently a decrease of blood flow to the cranial region. In designing a treatment for migraine, these authors combined finger-temperature-warming biofeedback with autogenic training. Autogenic training (Schultz & Luthe, 1959) involves the simultaneous regulation of mental and somatic functioning by meditation on passive activities, a form of relaxation and self-instruction (e.g., "My mind is calm and quiet"; "My arms are heavy and warm").

The temperature biofeedback is designed to help the patient learn to vasodilate the skin blood vessels. Sensitive thermisters are attached to the forehead and index finger of the hand on the side most frequently affected by migraine. Information regarding the differential temperature between the forehead and index finger is fed back to the patient.

Patients are instructed to use the autogenic phrases to induce increased finger temperature. In essence the training is designed to teach the patient to abort the vasospastic phase of the migraine attack.

In one of the first attempts to use biofeedback techniques to control migraine, Sargent and his colleagues (1972) provided 75 patients who reported various types of headaches (the number of migraine patients was unspecified) with portable biofeedback devices and pages of autogenic phrases for daily home practice. After mastering hand warming, patients were instructed to practice temperature control at home on alternate days without the biofeedback apparatus.

On the basis of self-reports of the amount of analgesic medication used and frequency and intensity of headaches plus independent clinical ratings, Sargent et al. reported that 74% of the patients, as assessed by psychologists, benefited from the autogenic biofeedback training. However, of the total sample of patients, adequate clinical ratings were available on 62 (again, the number of migraine sufferers was unspecified), and pretraining data were available for only 32 migraine patients. Thus the authors can only confirm some degree of clinical improvement in 29% to 39% of the original sample of 75 patients. The Sargent et al. results can be contrasted to the results of a study conducted by Mitchell and Mitchell (1971) that reported significant improvements in migraine headache activity in 71% of patients treated with relaxation and other behavioral approaches.

The methodology of the Sargent et al. (1972) study has been seriously challenged by Blanchard and Young (1974). They note the following:

> The procedures for evaluating hand-warming are unsatisfactory for three reasons: (1) little or no data on results are given and it is reported that the posttreatment results do not reach statistical significance; (2) the treatment package itself is a mixture of several factors, suggestion, relaxation training and biofeedback training, any or all of which may have accounted for the results; and (3) no-treatment or attention-placebo treatment control groups were not included. (p. 586)

Several other studies have investigated the relative efficacy of biofeedback training for the amelioration of migraine headaches (Friar & Beatty, 1976; Kewman, 1978; Medina, Diamond, & Franklin, 1976; Mitch, McGrady, & Iannone, 1976; Turin & Johnson, 1976).

Mitch et al. (1976) employed Sargent et al.'s (1972) autogenic feedback training with 20 migraine patients. Training was conducted over a 12-week period. During the first month of training, patients were instructed to practice with the biofeedback device 30 minutes each day. In the second month subjects were instructed to practice daily and whenever they identified the onset of headaches. Finally, during the last month of training, patients were to practice 1–2 times per week, at the onset of headache, and on the evening of the day a headache had occurred. For 10 patients, follow-up was conducted 6 months after the completion of training.

During the training period, patients maintained records on four dependent measures: duration, frequency, and intensity of headaches and amount of medication taken. Patients were also asked to report on perceived changes of symptoms at the end of the treatment period. These ratings were contrasted with reports of headache and medication use during the 6 months prior to training. Judgment of the efficacy of this procedure was based on improvements on the subjective headache incidence and medication use reports. The authors reported that 65% of the patients improved on two or more of the dependent measures. At the 6-month follow-up, 9 out of 10 patients reported average to excellent improvement compared to that in the 6 months preceding treatment, which suggests an ability to control headaches over an extended period of time.

The criticisms offered by Blanchard and Young (1974) concerning the Sargent et al. (1972) study (failure to identify the effective components of the treatment, failure to employ adequate controls, and failure to provide adequate statistical analysis) can be applied to the Mitch et al. (1976) study as well. The Mitch et al. study has a number of additional flaws that make interpretation of the results tenuous. The efficacy of the autogenic training was based on retrospective self-reports of headache incidence and cannot be considered a valid baseline against which to compare treatment efficacy. No attempt

was made to measure forehead or finger temperature prior to, during, or following training. Thus determination of the influence of the autogenic feedback training on underlying physiological processes cannot be established. Selection of the 10 patients included in the follow-up is not specified by the authors, and thus sampling bias may be introduced. In sum, the study is inadequate on a number of grounds and does not permit any conclusion regarding the efficacy of autogenic feedback training per se.

Medina et al. (1976) reported retrospective data on 27 patients with migraine or mixed migraine and muscle contraction headaches. In this study, relaxation training, frontalis EMG training, hand warming, autogenic phrases, and home practice all contributed to the treatment. As in the two preceding studies (Mitch et al., 1976; Sargent et al., 1972), patients were provided with portable biofeedback devices for home practice. Booster biofeedback sessions were provided every 2 months. At follow-up (an average of 10.7 months following the completion of training) the authors indicated significant reductions in the number and severity of headaches and the use of medication in 13 of the patients. Nine of these patients with migraines (64%) and only 4 (30%) with mixed migraine and muscle contraction headaches benefited from the treatment. The same methodological weaknesses found in the previous studies apply to the Medina et al. study.

The relative contribution of the autogenic phrases, a component of the autogenic feedback training package that was used in these three studies (Medina et al., 1976; Mitch et al., 1976; Sargent et al., 1972), was examined by Turin and Johnson (1976). Seven patients suffering from migraine headache were trained in the finger warming procedures with the autogenic phrases omitted. Patients recorded the frequency and duration of headaches as well as the medication taken during a 4–6-week baseline and throughout the study. Following the baseline period, the biofeedback training was conducted over a 6–14-week period. During each session the first 25 minutes was devoted to acclimating the patients to the apparatus. Finger temperature was recorded during this habituation period and during the 20-minute biofeedback training period. In addition, patients were instructed to practice the temperature control skills twice a day and at the first sign of a headache. In contrast with the Sargent et al. and Mitch et al. studies, no portable device was provided for the patients to use in home practice.

Turin and Johnson (1976) provided three of their seven patients with temperature cooling training for 6 weeks prior to temperature warming training. The authors reasoned that if both cooling and warming produced significant effects, then a placebo expectancy hypothesis could explain the data.

All seven of the patients learned the peripheral warming task rapidly. Of the three patients who received the temperature cooling training, none showed clinical improvement under this condition. Subsequent to the temperature warming training, all patients reported significant reductions in both headache incidence and amount of medication taken. These data are consistent with case studies that used analogous temperature cooling training and temperature warming paradigm (Johnson & Turin, 1975; Wickramasekera, 1973).

The results of a recent study, however, indicate that the effects of finger-temperature cooling on headache incidence is equivocal. Kewman (1978) trained one group of migraine headache sufferers to raise their finger temperature and a second group to lower finger temperature; a third group received no training, but they self-monitored and recorded headache incidence. Surprisingly, all three groups showed significant reductions in headache incidence. Obviously, the reduction in headache incidence cannot be attributed unequivocally to the specific effects of temperature warming biofeedback training.

The Turin and Johnson (1976) study is a much better designed and controlled study than the Sargent et al. (1972), Medina et al. (1976), and Mitch et al. (1976) studies. Adequate baselines were obtained and attention-placebo procedures were used. The results of the Turin and Johnson study question the hypothesis that the treatment results were simply a function of the relaxation, home practice, or autogenic phrases. The Turin and Johnson study also questions whether home

practice on a portable feedback device is necessary. The Turin and Johnson study is limited, however, by the failure to include any follow-up data, by the absence of controls, and by the failure to provide correlations between temperature reduction and decrease in headache incidence.

Thus the exact relationship between peripheral finger temperature and migraine headache remains obscure. In the Turin and Johnson (1976) study, reduction in finger temperature accounted for at most 25% of the variance in headache improvement and was essentially unrelated to decrease in the number of headaches. Such findings suggest that nonspecific treatment effects associated with finger warming training may account for a significant portion of the outcome obtained with this treatment (Miller, 1974; Shapiro & Surwit, 1976).

Finally, in a carefully controlled study, Andreychuk and Skriver (1975) compared finger-temperature biofeedback, biofeedback for electroencephalograph (EEG) alpha enhancement, and self-hypnosis. The alpha enhancement group was included as an attention-placebo control that included the use of the biofeedback ritual (actually a rather powerful, potentially useful approach, used with some limited success by Gannon and Sternbach, 1971, in a single case study of migraine control). Andreychuk and Skriver obtained baseline headache information for each patient for the 6 weeks preceding training. Each of the three groups then received 10 45-minute therapeutic sessions, and patients were asked to practice the various skills at least twice a day between laboratory sessions. The pretreatment data were contrasted with the patients' headache incidence during the last 5 weeks of the 10-week training period. All three groups showed significant reductions in the incidence of migraine headaches, with no significant differences between the groups. Unfortunately no follow-up data was collected, and thus no determination of the maintenance of headache reduction can be made from the Andreychuk and Skriver study. The authors also failed to provide information about alterations in physiological activity as a function of any of the training regimens.

The hypothesis that the efficacy of the temperature feedback training is attributable to the specific biofeedback training does not receive support from the Andreychuk and Skriver (1975) study. All three treatment groups shared a number of components, namely, relaxation, home practice, an expectancy for relief, and a fostering of a sense of control, each of which may have engendered change. Interestingly, Andreychuk and Skriver assessed the hypnotic susceptibility of each patient and noted that the degree of headache improvement reported was strongly related to hypnotizability. This correlational data raises some intriguing possibilities regarding the effects of individual differences in suggestibility on the efficacy of biofeedback training. Further examinations of the relationship between such individual difference measures and biofeedback training need to be conducted before any firm conclusions can be drawn.

Friar and Beatty (1976) used a different approach to the control of migraine headaches with biofeedback techniques. In contrast to the other studies reviewed, Friar and Beatty did not use finger temperature biofeedback training as their experimental treatment. Rather, patients were trained to decrease pulse amplitude in either the head (experimental group) or a peripheral site (hand control group). The authors inferred that training to reduce pulse amplitude in the peripheral site should produce only nonspecific effects and would not influence migraine incidence.

Nineteen migraine sufferers were included in the Friar and Beatty (1976) study. Baseline ratings of the frequency and intensity of headache and amount of medication were obtained from all patients. The training consisted of eight sessions extended over a 3-week period. No specific instruction for regular home practice appears to have been offered. A ninth, no-feedback session was conducted to assess patients' ability to control response independent of feedback. In this session, patients were instructed to produce the vasoconstriction that they had learned in the laboratory whenever they became aware of developing headaches.

Table 2
Summary of Studies That Examined the Efficacy of Biofeedback in Regulating Migraine Headaches

Effect of biofeedback on headache			Effects of biofeedback compared to comparison groups/conditions[a]			Concordance between physiological activity and headache incidence		
Significant	Nonsignificant reduction	Equivocal	No comparison	Superior to comparison	Equal to comparison	Concordant	Discordant	Not reported
Wickramasekera (1973)[b]	Gannon & Sternback (1971)	Sargent, Green, & Walters (1972)	Gannon & Sternbach (1971)	Wickramasekera (1973)[b]	Andreychuk & Skriver (1975)	Johnson & Turin (1975)[b]	Kewman (1978)	Gannon & Sternbach (1971)
Andreychuk & Skriver (1975)		Sargent, Walters, & Green (1973)	Sargent et al. (1972)	Johnson & Turin (1975)[b]	Kewman (1878)	Wickramasekera (1973)[b]		Sargent et al. (1972)
Johnson & Turin (1975)[b]			Sargent et al. (1973)	Friar & Beatty (1976)				Sargent et al. (1973)
Friar & Beatty (1976)			Medina et al. (1976)	Turin & Johnson (1976)				Andreychuk & Skriver (1975)
Medina, Diamond & Franklin (1976)			Mitch et al. (1976)					Friar & Beatty (1976)
Mitch, McGrady, & Jannone (1976)								Medina et al. (1976)
Turin & Johnson (1976)								Mitch et al. (1976)
Kewman (1978)								Turin & Johnson (1976)

[a] All groups that were not designed to provide contingent biofeedback training, are treated as comparison groups. These include relaxation, noncontingent biofeedback, and medication.
[b] No signficant analyses were reported, thus we can only assume that the effects were significant.

Friar and Beatty (1976) reported no statistically significant differences between the two groups in the number of headache episodes or in the rating of mean intensity of headache episodes. The groups did differ significantly in the number of major migraine attacks (defined as lasting 3 hours or more); the experimental patients had fewer headaches. The authors suggest that the purpose of training in vasoconstriction is to "abbreviate the headache attack rather than prevent the onset" (p. 51).

No correlational data between pulse amplitude and headache incidence is presented by Friar and Beatty (1976), nor do they present any information about pulse amplitude before or after training, which limits the determination of the relationship between pulse amplitude and intensity of migraine. It is not clear if the migraines were reduced significantly during training or whether the reduction was maintained after treatment. No long-term follow-up was reported. Although the Friar and Beatty approach looks promising, it awaits replications with more attention to maintenance of effects.

Table 2 contains a summary of studies that used biofeedback to ameliorate migraine headaches. A pattern of results similar to that observed with muscle contraction headache is also evident in the biofeedback studies with migraine headaches. Although biofeedback techniques do seem to reduce the incidence of migraine headache, training in muscular relaxation produces similar results.

An underlying feature of these biofeedback studies is the hypothesis that learned vasomotor control is central to effective treatment of migraine headaches. Unfortunately the experimental uncertainties and the lack of quantifiable data, and necessary control procedures present serious difficulties, making endorsement of biofeedback methodologies tentative at best. One problem in particular stems from the failure to demonstrate that reduction in headache incidence is correlated with alteration of peripheral vasodilation or pulse amplitude, a premise on which the biofeedback training is based. The absence of such demonstrated relationships should qualify endorsements of the therapeutic efficacy of biofeedback treatments. Such caution is indicated by the absence of (a) a careful consideration of the placebo effect and expectancy demands and (b) comparisons with other less expensive and more readily available treatment approaches (e.g., relaxation and self-control procedures). Many important issues remain unresolved, for example, evaluation of the training parameters, duration of treatment effects, and the role of individual differences.

Chronic Pain Other Than Headache

In contrast to the host of studies that examined the effects of various biofeedback approaches for headaches, relatively few investigations have applied biofeedback techniques to other forms of chronic pain. Unsystematic case studies that reported the efficacy of biofeedback for chronic pain have been offered by Coger and Werbach (1975) and by Gentry and Bernal (1977). Other investigators have incorporated biofeedback into a variety of other procedures but have not assessed the contribution of the biofeedback training alone (e.g., Gottlieb et al., 1977; Newman, Seres, Yospe, & Garlington, 1978; Seres & Newman, 1976; Swanson, Swenson, Maruta, & McPhee, 1976; Khatami & Rush, Note 1).

Recently, two studies (Hendler, Derogatis, Avella, & Long, 1977; Melzack & Perry, 1975) have specifically examined the efficacy of biofeedback with groups of chronic pain patients. Hendler et al. used EMG biofeedback with chronic pain sufferers. They used frontalis EMG training for two reasons. First, Bonica (1974) had suggested that stress and anxiety could induce reflex muscle spasm, vasomotor changes, and local ischemia and thereby exacerbate pain syndromes that involved muscles, tendons, and reflex muscle spasms. Second, Budzynski and Stoyva (1969) had suggested that frontalis EMG relaxation was an indication of generalized muscle relaxation.

Thirteen patients suffering from a variety of pain syndromes were treated by Hendler et al. (1977) with five sessions of frontalis EMG feedback training. At a 1-month follow-up 6 patients reported that they were obtaining continued relief. The other 7 patients reported no benefit from the biofeedback training. No control procedures were used,

nor was specific information provided regarding the length of baseline and initial posttreatment and follow-up levels of EMG. Hendler et al. reported the absence of a significant correlation between muscle tension and reduction of pain. The absence of a relationship questions the conclusion that frontalis EMG training contributed to pain reduction. Hendler et al. concluded that

> the beneficial effects of biofeedback for these responders may be explained in terms of an increased sense of mastery over their environment, which resulted in a reduction of obsessive concern about their somatic problems and improvement in their self-esteem as a result of their increased environmental control. (p. 508)

Such a conclusion must be viewed only as a speculation, but a speculation that has been voiced by Lazarus (1977) and Meichenbaum (1977), who have also stressed the role of cognitive factors in biofeedback training.

In the second study that examined the efficacy of biofeedback in the reduction of chronic pain, Melzack and Perry (1975) compared the relative effects of EEG alpha biofeedback, hypnotic training, and a combination of both alpha and hypnotic training. The hypnotic training focused on increasing relaxation, energy levels, and mental calmness and on a reduction in the level of worry prior to the patients becoming upset. Six patients received the alpha feedback, 6 received self-hypnosis training alone, and 12 patients received the combined training. All three groups showed increased levels of alpha activity. The groups who received combined biofeedback and hypnosis training or hypnotic training alone demonstrated substantial reductions in pain compared to baseline. Patients who received the alpha training alone showed virtually no change in pain. These data suggest that the cognitive approach of hypnosis may be effective in reducing pain from unbearable to bearable levels but provide no support for the efficacy of EEG alpha biofeedback training as a tool in reducing pain. As Melzack (1975) suggested in the subtitle of his article that reviewed biofeedback approaches to reduce chronic pain, "Don't Hold the Party Yet." We concur!

Summary and Conclusions

What conclusions can be drawn from the studies that examined the efficacy of biofeedback for the regulation of pain?

1. The relationship between the experience of pain and the various physiological responses that biofeedback techniques are designed to control has not been established. Without the determination of some relationship between a physiological response and the experience of pain, the rationale for selecting a physiological function for voluntary control remains unclear.

2. Although it seems likely that most individuals can acquire some degree of voluntary control over autonomic functioning with biofeedback training, there are large individual differences among subjects. Investigations of the utility of biofeedback for pain regulation suffer from both "patient and treatment uniformity myths" (Kiesler, 1966, p. 129). Simply stated, investigators have treated all patients, regardless of individual differences, with ostensibly the same biofeedback therapy.

3. Many health care providers view biofeedback methodology as some unified therapeutic treatment. In actuality, biofeedback is a generic term for a wide range of approaches, which include some form of biological feedback that is intended to increase voluntary control of physiological responses. The question "Is biofeedback effective for regulating pain?" should be replaced by the questions "What combination of cognitive, behavioral, and biofeedback approaches would benefit which patients, with what symptoms, under what circumstances, and at what expense?" The present review questions the relative efficacy of biofeedback training in comparison with other more readily available methods. The promissory fanfare (and hoopla) that has accompanied biofeedback training has not yet been fulfilled. Some beginnings and some potential have been identified, but endorsements should be proffered with caution and qualification.

4. The active ingredients of biofeedback therapy have not been identified. The necessary and sufficient components of such a multifaceted approach as biofeedback have not been established.

5. Effective control procedures have not been used in the majority of studies. The inclusion of appropriate control groups is essential in the study of such conditions as migraine and muscle contraction headaches for several important reasons. Two sources of rival hypotheses that can be offered to explain the efficacy of biofeedback training are the regression-to-the-mean problem and the placebo effect. Miller (1974) argued that patients are much more likely to seek treatment when they are feeling worse. Since physiological systems tend to fluctuate between periods of exacerbation and those of amelioration, it is possible to obtain a sample of volunteers whose pain will show reduction due to spontaneous fluctuation, regressing toward the mean level. This point also underscores the necessity of incorporating extended follow-up periods to assess relative efficacy of biofeedback training.

Placebo effects are potent factors in any treatment of pain (Beecher, 1959; Evans, 1974; Ostfeld, 1961; Shapiro, 1963) and are especially potent in an impressive treatment such as biofeedback, with its complex mechanical equipment. The important potential role of placebo effects indicates the need for conducting double-blind studies that include credibility checks of patient expectancies (see Kazdin & Wilcoxon, 1976). The studies that have used feedback that involved temperature warming and cooling groups comprise a needed step in this direction.

6. There is relatively little information available concerning generalization of learning from the laboratory or clinic to the natural environment over extended periods of time. In many of the biofeedback studies, patients are instructed to become aware of the onset of headaches or some other physiological condition, but little or no attention is directed at what this entails. A more careful analysis of these processes should enhance the generalization process. A related issue is the need for more careful study of the dependent measures that have been employed in biofeedback studies. Three classes of measures have been used, namely, measures of physiological changes such as EMG, self-report ratings (e.g., headache intensity), and amount of medication. Much more concern should be directed at specifying the variables such as demand characteristics, scoring formats, and so forth, that influence the latter two measures. A much more careful analysis of these indices will provide implications for treatment interventions (see Frederiksen, Lynd, & Ross, 1978).

7. It is clear that pain conditions cannot be viewed as independent phenomena represented simply by maladaptive physiological responding. The particular physiological data gathered on any given day is a response determined by situational and diurnal variations and complex physiology and personality characteristics, as well as the particular environmental context. All of these factors need careful research consideration, particularly in view of the stress-producing potential of various environments (Insel & Moos, 1974). Research is needed to evaluate the interactions between situational effects and the person variables that contribute to individual differences in response to stress.

8. The focus of biofeedback training has been on increasing one's awareness of maladaptive physiological response by means of feedback and on developing voluntary control by conscious effort. As with any therapeutic regimen, biofeedback requires compliance over time. The question at the simplest level is how to motivate the patient to spend the necessary time practicing the desired behavior, especially when the novelty wears off. The problems inherent in convincing patients to continue to use prescribed medical or training regimens has been discussed by Agras (Note 2), Blackwell (1972), and Marston (1970).

9. Biofeedback training places the greatest emphasis on maladaptive physiological functioning. But this is a too restrictive view of pain. In pain syndromes, consideration must also be given to the patient's coping patterns and life style (Genest & Turk, 1979). Teaching voluntary control of physiological functioning may not be sufficient, since patients not only must control their physiology but they must be capable of dealing effectively with their environment (Shapiro & Schwartz, 1972). It may prove more feasible to consider biofeedback as an adjunctive technique to be used with other physiological and psychological approaches rather than as the sole

treatment modality (cf. Genest & Turk, 1979; Gottlieb et al., 1977; Mitchell & White, 1977; Turk & Genest, 1979; Khatami & Rush, Note 1). Training in the use of self-control strategies should enhance the utility of biofeedback techniques and should foster generalization beyond the relatively non-stress-producing, quiescent laboratory setting. (See Goldfried & Trier, 1974; Meichenbaum, 1977; Meichenbaum & Turk, 1976; Turk, 1977, for examples of such self-control interventions.)

10. The reviewed studies reveal a consistent lack of concern for the subjects' appraisals of the biofeedback techniques. What does the patient think of the training, and how does the patient use the skills acquired? These questions are rarely addressed in the literature. (cf. Meichenbaum, 1976, for a discussion of this issue.) Examination of patients who fail to benefit from biofeedback training and analyses of those patients who prematurely drop out of training would provide valuable information. The presentation of group data often tends to obscure individual differences in the ability to benefit from the training. Examination of single subject data would help to answer some of the questions raised previously.

In sum, the biofeedback studies reviewed do not yield consistent results. The evidence for the efficacy of biofeedback per se in reducing pain is marginal at best, resting mainly on case studies and poorly controlled research.

In drawing this conclusion, it is important to recognize that the diagnosis of various types of pain disorders is less than reliable. The lack of such reliability tends to limit the efficacy of any treatment, including biofeedback. Although the present review focused on chronic pain, similar conclusions can be offered about the questionable value of biofeedback with hypertension (Surwit, Shapiro, & Good, 1978) and even in the control of heart rate (White, Holmes, & Bennett, 1977). In some cases the evidence indicates that cheaper, more readily available relaxation and coping skills interventions are as effective or more effective than biofeedback training. Moreover, one cannot conclude from the aggregate of biofeedback studies that physiological feedback training per se is an indispensible (or even necessary) part of the therapeutic regimen. The only conclusion that seems warranted at this time is that one or a combination of the components of biofeedback training is an effective method of pain regulation for some patients in certain situations. Studies to date have dealt with diverse populations, a variety of biofeedback approaches that contain a number of potentially active components, and a wide array of research designs. Consequently, generalizations must be tentative. Current enthusiasm for biofeedback methodology must be tempered with an appreciation that the approaches are still experimental, with many issues as yet unexamined. Evidence for the widely acclaimed benefits of biofeedback is lacking, and biofeedback should be considered only a research tool at this time. Caution must be maintained to prevent the misapplication of biofeedback techniques.

Asymmetries in Processing Auditory Nonverbal Stimuli?

J. D. Craig
U. S. Army Human Engineering Laboratory, Aberdeen, Maryland, and
University of Delaware

Reports in recent psychoacoustical literature have suggested that pitch and rhythm properties of nonverbal stimuli may be processed differently by the two cerebral hemispheres. A review of this literature and pertinent background information generated the following conclusions: (a) Perception of pitch stimuli probably does not require differential cerebral processing. Only when some type of novel or complex time structure is generated in the stimulus presentation do the responses of subjects reflect a cerebral dominance effect. (b) The asymmetries demonstrated in the results of rhythm experiments closely parallel those found in verbal experiments. In addition, rhythm structure may also provide a framework for the synthesis and analysis of all incoming perceptual information. Further research on the properties of nonverbal auditory stimuli may add substantially to our knowledge of polysensory human information processing.

Recent psychoacoustical literature has suggested that pitch and rhythm properties of nonverbal stimuli may be processed differently by the two cerebral hemispheres. The present state of the art provides an unclear and sometimes conflicting picture of how either rhythm or frequency perception is related to cerebral dominance.

Some of the earliest studies in neurophysiology demonstrated that there were large differences in the functions of equivalent areas within the two cerebral hemispheres. In 1861 Paul Broca published a series of papers on language and the brain (cited in Geschwind, 1972). He identified the third frontal gyrus of the cerebral cortex as the area that when damaged, caused language deficiencies such as slow labored speech but did not affect comprehension of spoken language. Broca further reported that speech disorders occurred only when this area in the left hemisphere was damaged; damage to the corresponding structures in the right hemisphere did not produce corresponding clinical symptoms. The unequal specialization of the two halves of the brain became known as cerebral dominance.

Approximately 15 years later, Carl Wernicke described another language disorder (cited in Geschwind, 1972). Clinical symptoms included both quick articulate speech that was devoid of meaningful content and severe loss of understanding of spoken verbal material. Posthumous examination of the brains of these patients revealed lesions located between Heschl's gyrus and the angular gyrus in an area adjacent to the cortical auditory region. This area, now known as Wernicke's area, was located in the left hemisphere for most patients; damage to the equivalent area in the right hemisphere did not cause equivalent behavioral deficits.

Wernicke proposed a model of how this area interacted with Broca's area to provide normal speech capabilities. The key points of this model are as follows: (a) When a word is *heard*, it is conveyed to the auditory cortex, then relayed to Wernicke's area, where comprehension occurs. If the word is to be spoken, it is further conveyed to Broca's area via the arcuate fasciculus, a large band of fibers that connects the two regions. In Broca's area the spoken form of the word is aroused and passed on to the motor area that controls the muscles of speech. (b) When a word is *read*, output from

the visual cortex is relayed to the angular gyrus and further to Wernicke's area. In Wernicke's area the auditory form of the word is aroused and processing continues as described above. In terms of clinical value, this model has been effective in predicting which areas of the brain are involved in specific language disorders (Geschwind, 1972).

One of the most important findings in these early studies was that only one side of an individual's brain seems to be involved in language processing. For the vast majority of the patients studied, damage to the left hemisphere resulted in the language disorders described, whereas patients with equivalent damage to the right hemisphere did not develop language deficits. For a small percentage of the population, the opposite condition exists; that is, language abnormalities develop only when there is damage to the right hemisphere.

It was further noted that the great majority of right-handed persons were also left dominant for speech; that is, lesions in the left hemisphere of right-handed persons produced language disorders. However, cerebral dominance of the left-handed person was not nearly so well-defined; the left-handed person could be either right or left dominant for language functions. Currently accepted studies that correlate cerebral dominance with handedness indicate that 99% of all right-handed persons are left dominant for speech (Rossi & Rosadini, 1967), whereas for approximately half of all left-handers, language functions appear to be localized in the right hemisphere (Goodglass & Quadfasel, 1954). It is also accepted that lateralization of cerebral dominance is less clearly defined in left-handed persons. In many behavioral studies this correlation between handedness and cerebral dominance has been used as a convenient means for assuming cerebral dominance in a subject. This assumption is probably more valid for right- than for left-handed persons.

Since the landmark studies by Broca and Wernicke, a great deal of effort has been expended in attempting to define the exact nature of cerebral dominance. A short, selective review of both physiological and behavioral studies is provided here, with emphasis on the research that provides a perspective for current studies of asymmetrical processing of nonverbal auditory stimuli.

Physiological Studies

The central auditory system in both humans and animals is physically a bilaterally projecting system. However, most of the stimulation received by either ear is conveyed to the opposite temporal cortex via the strong contralateral auditory pathways. Much of the information that does reach the ipsilateral cortex is derived from input that has traveled along the contralateral pathway and been redirected back to the side of original stimulation. The secondary and efferent pathways are so complex that many details concerning them are still uncertain (Carpenter, 1976). Nevertheless, it is clear that the auditory pathways function as a primarily contralateral system.

Dominance is usually associated with the cerebral hemispheres only. Although much information on the anatomy of the brain has been derived from animal studies, research on cerebral asymmetries using animal subjects is still considered by some writers to be of questionable value because many of the behavioral manifestations of cerebral dominance, like language function, are absent in animals. Summarizing the evidence presented by several investigators concerning lateralization in animals, in particular "pawedness" in cats, rats, and primates, Jung (1962) concluded that "real hemispheric dominance does not occur in any of these infrahuman species" (p. 268).

Since that time, the most compelling evidence for cerebral dominance in animals is found in the experiments of Nottebohm (1970). He found that the pattern of song in chaffinches and canaries is largely destroyed if the left hypoglossal nerve is lesioned but remains undisturbed when the right hypoglossal nerve is cut. His inference was that birdsong is primarily controlled by the left side of the brain in these birds.

In addition to the uncertainty that exists concerning the value of animal experiments in this area, there has been some question until recently whether there are structural asymmetries in the human brain that can be correlated with the functional asymmetries noted earlier. For many years it was generally ac-

cepted that the language dominance found in humans is not associated with any significant differences in anatomy between the right and left hemispheres. Von Bonin (1962) reviewed a large number of studies on this subject and concluded that "these morphological differences are, after all, quite small. How to correlate these with the astonishing differences in function on the left side, is an entirely different question" (p. 6).

In 1968 Geschwind and Levitsky published the results of their postmortem examinations of 100 adult human brains. The hemispheres were divided and each hemisphere was sectioned along the plane of the sylvian fissure to expose the upper surface of the temporal lobe. They found that the planum temporale was larger on the left for 65% of their specimens and on the right for 11% ($p < .001$), but 24% of the specimens showed equality of the two sides. This is important because the planum temporale contains the auditory association cortex. (The primary auditory cortex is located in Heschl's gyrus.) In the dominant hemisphere, these regions of the auditory association cortex are the classical Wernicke's area. Unfortunately, no information was available about the cerebral behavioral dominance or handedness of the living subjects. However, since 93% of the adult population is right-handed, the authors concluded with some small tolerance that they were probably working with left-dominant specimens. Their conclusion was as follows:

> Our data show that this area is significantly larger on the left side, and the differences observed are easily of sufficient magnitude to be compatible with the known functional asymmetries. (Geschwind & Levitsky, 1968, p. 187)

Recently, Yeni-Komshian and Benson (1976) have reported that chimpanzee brains have a similar asymmetry but to a lesser degree than do human brains. The brains of rhesus monkeys did not show any significant differences between the right and left temporal lobes. Since there have been demonstrations of some language capability among chimpanzees, these investigators suggested that neuroanatomical asymmetry may be a prerequisite for language functions.

To date, however, the Geschwind and Levitsky (1968) research is the most definitive study available on the anatomical asymmetries that may be associated with the functional differences found in human clinical and behavioral studies.

Behavioral Studies

The behavioral studies of the role of cerebral dominance in auditory perception are almost exclusively dichotic-listening experiments. Dichotic listening is a technique in which different inputs are simultaneously delivered to the right and left ears.

Kimura (1961) adapted the dichotic method to the study of the cerebral dominance effect in audition. She showed that when two digits are simultaneously presented to the two ears of a normal subject, digits arriving at the ear contralateral to the dominant hemisphere are more readily recognized than those arriving at the ipsilateral ear. At the end of her study, she concluded that the crossed auditory pathway from the contralateral ear to the speech hemisphere is more effective than the slightly smaller uncrossed pathway from the ipsilateral ear and that the dominant temporal lobe is more important than the nondominant temporal lobe in the perception of speech.

In a later study Kimura (1967) noted that in auditory studies, a cerebral dominance effect is evident only when there is simultaneous input to the two ears, that is, when dichotic presentation is used. Laterality, or ear superiority, is not evident when identical material is presented monaurally. If there is only one source of stimulation at a time, each ear performs equally well. Summarizing the difference between the dichotic and monaural studies, Kimura proposed that the cerebral dominance effect is the result of competition between simultaneous inputs to opposite cerebral hemispheres. When there is dichotic stimulation to the two hemispheres, competition between the coincident stimuli automatically occurs. Superior responses to the stimuli presented to the dominant hemisphere result from the conflict between the disparate perceptions of the two hemispheres.

This conclusion went somewhat beyond the data presented, and shortly thereafter several efforts were made to disprove it. In particular, two major objections were tested. The first

objection to Kimura's (1967) hypothesis focused on the role of memory. Laterality in response might be due to asymmetries in recall rather than to asymmetries in perception. The objective, then, was to separate the perceptual from the storage or response phases of the dichotic listening method.

Bryden (1967) conducted a series of experiments to study this issue. He suggested that the material from the ear that was reported first would be identified more accurately than material from the other ear. This would occur because the time elapsed decreases the accuracy of memory for the second channel. Therefore, a tendency to consistently report material from a preferred ear would account for the laterality effect, even if initial perception of material to both ears were equal. He examined the difference between free recall, in which the subject was allowed to report material from either ear at will, and ordered recall, in which the subject was required to report all material from one or the other ear first.

He found a high correlation between right-ear advantage in free recall and right-ear dominance in ordered recall. His data indicated that material presented to the right ear was more accurately identified than material presented to the left ear. (He had primarily used right-handed subjects.) This was true for all rates and list lengths investigated. When the two ears were compared as channels of immediate recall, the right ear was superior to the left. Also, the right ear was better as a storage channel than the left. In addition, there was a general tendency to report the right ear first. He concluded that the data supported the notion that right-ear superiority is due to a perceptual difference rather than to an order effect. This conclusion clearly supports Kimura's (1967) hypothesis that the cerebral dominance effect is a result of competition between simultaneous inputs to the two cerebral hemispheres.

The second objection to Kimura's (1967) hypothesis concerned the role of attention in the results of dichotic listening studies. Bryden (1969) tested a hypothesis that the laterality effect obtained by Kimura was due to division of attention rather than to competition of simultaneously arriving stimuli. In the first experiment subjects listened to monaural stimuli but had no prior knowledge of which ear would receive the next stimulus (monaural presentation with division of attention). Responses in these conditions showed no laterality whatsoever.

Bryden (1969) further tested his subjects using dichotic input under two different conditions. In the first condition, subjects were told to which ear to attend; therefore, they ostensibly were attending to only one channel while receiving competitive stimulation through both ears. In the second condition, subjects were not told to which ear they should attend; this condition offered both stimulus competition and division of attention. In both of these conditions a statistically significant laterality effect was obtained. To summarize, regardless of instructions or deliberate direction of attention, lateralization of response occurred in the dichotic listening paradigm. Bryden concluded that these results supported Kimura's (1967) hypothesis that the laterality effects obtained in dichotic listening experiments are due to signal competition rather than to attention factors.

Another variation of the dichotic listening studies of cerebral asymmetry is the research in which pathological subjects have been used. Milner, Taylor, and Sperry (1968) found that right-handed commissurotomized patients (those who have surgical disconnection of the cerebral hemispheres because of epilepsy or other reasons) could not report verbal input to the left ear if a different verbal input was simultaneously delivered to the right ear. However, all known auditory pathways remained intact and the subjects could report with total accuracy monaural input to either ear.

The results of this study were duplicated by Sparks and Geschwind (1968). A review of the data led them to propose another model for dichotic auditory asymmetries, which incorporated Kimura's (1967) model but suggested in addition a callosal auditory pathway between the two cerebral hemispheres. This model could account for the cerebral dominance effect evident in normal subjects and the left-ear suppression by right-handed commissurotomized patients in dichotic studies. The main points of this model were as follows:

1. In dichotic listening contralateral ear input virtually suppresses ipsilateral input.

2. There is competition for report by the left-hemisphere speech system between information arriving directly from the right ear via the contralateral pathway and information from the left ear.

3. Since information from the left ear has also traveled along a contralateral pathway to the right hemisphere, it must in addition be projected to the left hemisphere for report. This projection probably involves a callosal pathway.

In a further study, Sparks, Goodglass, and Nickel (1970) used this model to explain data gathered from left-brain-injured aphasic patients and right-brain-injured nonaphasic patients. The right-brain-damaged group could not report the signals received by the left ear after listening to dichotic verbal stimuli. However, the left-brain-damaged group was divided between those who experienced inhibition of right-ear input and those who experienced inhibition of the left-ear input. One possible explanation for these results was that competition between signals received by both ears occurs exclusively in the left hemisphere. Therefore, they revised the earlier model to state that only damage to the left hemisphere can affect information from either the contralateral or ipsilateral ear.

No review of the literature that deals with cerebral asymmetries and audition is complete without some mention of the studies that have concentrated on the functions of the minor hemisphere. Originally this work began by drawing an analogy from studies of cerebral asymmetries in vision. These studies showed that damage to the nondominant temporal lobe produced impaired performance on many visual, nonverbal tasks. A natural extension of this work was to determine if such a division of function also existed in the auditory modality.

Milner (1962) examined the effects of temporal lobectomy on nonverbal auditory discriminations. Her subjects were left dominant for speech; in addition, each subject had a lesion in either the right or left temporal lobe. These subjects responded to the Seashore Measures of Musical Talents, which included tests for pitch, loudness, rhythm, time, timbre, and tonal memory. Her data showed that the group with right temporal lesions made more errors than the group with left temporal lesions. The difference between the two groups was strongest for tonal memory and timbre. This research definitely indicates that the right hemisphere is strongly involved in processing certain types of musical sounds in left-dominant subjects.

Later, Kimura (1964) verified these results using normal subjects. Her rationale was that if the nondominant hemisphere is more strongly involved in certain musical abilities than the dominant, then normal subjects who show right-ear advantage for verbal materials should also show a left-ear advantage for musical material. This reasoning was based on a knowledge of the strong contralateral auditory pathways and was consistent with her model for dichotic auditory processing.

In preliminary tests, subjects listened to different numbers of clicks presented simultaneously to both ears. They were required to report the number of clicks presented to each ear. The subjects responded with a small but nonsignificant bias in favor of the left ear. She then presented melodic patterns dichotically. Left-ear melodies were reported correctly significantly more often than right-ear melodies ($p < .01$). Kimura (1964) concluded on the basis of these data and Milner's (1962) studies that the difference in function between major and minor hemispheres is along a verbal–nonverbal dimension. Kimura also noted that this asymmetry is obtained only in dichotic listening conditions.

Kimura's model provided a simple, easily applied paradigm for explaining large groups of existing data and experimental results. One of the first aspects of the model to receive attention concerned the meaningfulness of stimuli. Curry (1967) investigated this problem in a three-condition task using dichotic words (meaningful verbal), dichotic nonsense syllables (nonmeaningful verbal), and dichotic environmental sounds (nonverbal). His subjects were instructed to identify both stimuli in a free-recall paradigm. They obtained higher scores for right-ear stimuli when both words and nonsense syllables were used but higher left-ear scores with the nonverbal stimuli. This study shows that meaningfulness is not critical for the functional division ob-

tained in this and in other studies and supports Kimura's model.

Shortly after this time, research began to appear which indicated that the situation is not a simple dichotomy of function. Studdert-Kennedy and Shankweiler (1970) presented data which suggest that consonants are processed by the left hemisphere, whereas vowel sounds are processed by both hemispheres. The stimuli were spoken consonant–vowel–consonant syllables presented in dichotic pairs. For any pair of stimuli, only the initial consonants, the final consonants, or the vowels differed. Subjects were tested separately for each of the three types of stimuli. They were told to report both initial consonants in the dichotic pair, both final consonants, or both vowels. Significant right-ear advantages were obtained for the initial ($p < .001$) and final ($p < .01$) consonants. Data showed mixed ear superiority for the vowel sounds, which suggests that both hemispheres are involved in speech analysis.

Studies that investigated the processing of nonverbal dichotic stimuli also report a complex division of function. These studies suggest that different acoustical attributes of nonverbal stimuli are differentially processed by the cerebral hemispheres. Spellacy (1970) found a significant left-ear advantage for dichotic melodies but found no significant difference between ears for timbre, temporal, or frequency patterns. Stimuli used for the melodies test were unfamiliar violin solo melodies. Frequency patterns were composed of four 500-msec consecutive tones. Each tone was of a different frequency and all tones were between 440 Hz and 880 Hz. Temporal stimuli were tone pulses arranged in Morse code patterns. Timbre stimuli consisted of single notes played on a pipe organ, using varying combinations of pipes. After listening to the dichotic test stimuli, subjects listened to binaural identification stimuli and then reported whether the identification stimulus matched either of the test stimuli.

Gordon (1970) also attempted to separate the different acoustical qualities found in many nonverbal stimuli. He devised two tests for his subjects. The first consisted of melodies largely devoid of timbre and chordal properties. The second test consisted of electric organ chords that were rich in timbre. The first test therefore varied pitch over time to produce melodies; the second test avoided melodic sequence. Gordon's results, in contrast with those of Spellacy (1970), showed no asymmetry in recognizing and reporting the melodies but showed a strong left-ear advantage in the chords test.

One of the things that makes this report by Gordon interesting is his explanation of these results. He noted that it is impossible to rule out a hypothesis that rhythm may be lateralized to the left hemisphere:

> [A] predominance of rhythmic function in the left hemisphere coupled with the function of pitch discrimination in the right hemisphere could produce the observed results and confound the conclusions. The subjects would recognize unique rhythms in some trials and unique melodic changes in others so that the overall performance [on the melodies test] would show no asymmetry. (p. 395)

Pitch Processing

Deutsch (1974) also reported some highly unusual data. She described perceptions of certain dichotic pitch patterns as "auditory illusions" because they differed considerably from the actual physical stimuli presented. She reported that perception of these illusions was related to the handedness and presumed cerebral dominance of the subjects. The illusion was based on opposing octave pitch patterns and is hereafter called the "octave illusion."

The octave illusion occurred under the following conditions. A sequence of tones was presented to one ear, alternating in frequency between 400 Hz and 800 Hz. Tone duration was 250 msec and there were no intervals between tones. The opposite ear received an equivalent sequence simultaneously at equal amplitude. However, the sequences to the two ears began on opposite frequencies, so that simultaneously, a 400-Hz tone was presented in the right ear and a 800-Hz tone was presented to the left ear.

None of the 86 subjects accurately reported the stimuli. Right-handed subjects had a tendency to hear a single tone oscillating from ear to ear; the pitch of the tone also oscillated from one octave to the other. Approximately half of the left-handed subjects reported this

pattern, too. However, 39% of the left-handed subjects reported complex perceptions, for example, two alternating pitches in one ear with a third pitch intermittently in the other or two alternating pitches oscillating from ear to ear and two further alternating pitches localized at the back of the head. Right- and left-handed subjects differed significantly in the relative distribution of their percepts.

Deutsch (1974) further reported that right-handed subjects had a significant tendency to report the high tones in the right ear and the low tones in the left ear. However, she indicated that this localization pattern often reversed with continued listening, much as perceptions of ambiguous visual patterns reverse.

Not all investigators agree on the role of cerebral asymmetries in the processing of pitch information. In particular, Efron and Yund (1976) reported data in which subjects favored one ear or the other in reporting certain dichotic chords but found no correlation between the favored ear and the cerebral dominance of their subjects. They described results of this type as an "ear dominance effect."

A typical example of the type of stimulation used by Efron and Yund (1976) in many experiments was as follows: One ear received a 1900-Hz tone for 320 msec; after a 4-msec interval, a second 320-msec pure tone of 1500 Hz was presented (high–low pattern). The opposite ear received simultaneous tones, with the order of the frequencies reversed (low–high pattern). Subjects reported whether the pitch of the first chord was higher or lower than that of the second. Describing their results across many experiments, Efron, Dennis, and Yund (1977) stated that

> although both frequencies comprising the dichotic chord are heard by all subjects with normal hearing, only one-third of the subjects hear the two frequencies with approximately equal salience. For another third of the population, the pitch mixture of the dichotic chord is unequivocally dominated by the frequency delivered to the left ear; for the final third of subjects, the frequency of the tone presented to the right ear dominated the pitch mixture of the dichotically presented chord. (p. 538)

The distribution of these data does not correspond to any known factor related to cerebral dominance or handedness. In addition, Efron and Yund (1976) investigated the relation of ear dominance to the handedness of their subjects. They found that there was no correlation with handedness when dichotic tones of about 1700 Hz were presented to the subjects.

They further suggested that the difference between their data and those reported by Deutsch (1974) might be due to the higher frequency of their stimuli. Deutsch used stimuli in the 400 to 800 Hz range, which is within the frequency range of speech vowel sounds. Although Stevens and House (1972) summarized data which show that important features of the speech frequency envelope range from 300 to 3000 Hz, Efron and Yund (1976) concluded that "correlation between ear dominance for pitch and handedness (hemispheric dominance for speech) exists only in the frequency band which carries speech information" (p. 898). We must assume that they were referring to the frequency band for vowel sounds.

Such a hypothesis did not go unnoticed. Christensen and Gregory (1977) reported an experiment designed to examine the ear dominance effect in the speech vowel frequencies. They used 400- and 800-Hz tones in an experimental paradigm that closely resembled that used by Efron and Yund (1976). Subjects received two consecutive pairs of tones. Tones lasted 250 msec; one channel consisted of a 400-Hz tone followed by an 800-Hz tone, whereas frequencies were reversed for the second channel. Most subjects perceived only a single tone from each of the dichotic pairs. This is similar to Deutsch's (1974) results. However, in agreement with Efron and Yund's results, they found no evidence of any type of a cerebral dominance effect in the responses.

From the previous review it is apparent that there is in the literature a dichotomy pertaining to pitch processing. When some dichotic pitch stimuli are presented, asymmetries in response show a relationship with handedness; when other dichotic stimuli are used, no relationship between handedness and responses is found. Since both sets of stimuli were designed to study pitch processing, it is unclear why this happens. It is possible that one of the paradigms may be unwittingly contaminated by the inclusion of some factor other than simple pitch discrimination. If this is true, then there

is a possibility that the presence of a cerebral dominance effect in one group of data and an unrelated ear dominance function in the other group is due to some factor other than differential pitch processing.

There are two major dimensions present in any acoustical pattern: pitch and time. The two dimensions are probably inseparable on an absolute basis. When we speak of frequency, we describe sound as a certain number of cycles per second. When we speak of any type of acoustical time or rhythm pattern, the elements of that pattern are composed of specific frequency profiles. In dichotic listening experiments, study of one dimension has been accomplished by exactly matching the other dimension in both ears. For example, in both the Deutsch (1974) paradigm and the Efron and Yund (1976) paradigm, the on–off times of stimuli to opposite ears are exactly synchronized, whereas only the frequency of the stimuli presented to each ear varies.

However, there is another time-related variable that is introduced in comparisons of the two sets of stimuli: the number of frequency changes or transitions in each pattern. Halperin, Nachson, and Carmon (1973) found a shift in ear advantage related to the number of frequency and duration transitions within temporally patterned nonverbal stimuli. They found that as the complexity of the pattern increased (the number of transitions within the pattern), there was a shift from left- to right-ear superiority with right-handed subjects.

In the Deutsch (1974) paradigm there are approximately 20 frequency transitions in each channel within a 5-sec stimulation period. Deutsch and Gregory (1978) have confirmed that no cerebral dominance effect is obtained when the octave stimuli are not part of long repetitive sequences of tones. The number of transitions in the Efron and Yund (1976) paradigm is much smaller. In view of the data presented by Halperin et al. (1973), the strong cerebral dominance effect achieved with the Deutsch octave stimuli may be due to the high number of transitions. If this is true, then the cerebral dominance effect evident in the octave illusion may depend more strongly on time variables than on pitch variables.

Rhythm Processing

Relatively little is known about the way in which dichotic time patterns are processed. Milner (1962) found a significant increase in error scores after right temporal lobectomy on the time test of the Seashore Measures of Musical Talents, which require the subject to judge the relative duration of two consecutive tones. Although this is not a dichotic listening task, Milner's data suggest that the right temporal lobe is involved in duration discrimination.

Spellacy (1970) reported that there was no preference for either ear when subjects responded to dichotic Morse code patterns. However, in his experiment the two channels were presented at different frequencies (1000 Hz and 1500 Hz) to maximize discrimination. It is possible that by introducing frequency differences between the ears, Spellacy's data reflect the complex interaction between time and frequency suggested by Gordon (1970). In other words, an opposing cerebral dominance effect for each of these variables might cancel the effects of both.

Robinson and Solomon (1974) presented right-handed subjects with dichotic rhythm patterns that consisted of from four to seven, short or long, sine wave pulses. The dichotic patterns were presented to subjects at matched frequencies, with simultaneous onset and offset of the two patterns. The data supported a hypothesis that rhythm is processed by the left hemisphere in most right-handed subjects. A similar hypothesis was satisfactorily defended by Gordon (1978), using rhythmic elements in dichotic melodies. This is interesting in view of the earlier model for dichotic listening proposed by Sparks et al. (1970). In this model competition between signals received by both ears occurs exclusively in the left hemisphere of left-dominant subjects.

An attempt to interpret the results of the rhythm experiments meets with a number of difficulties. One such problem concerns the population tested. Subjects used were right-handed or presumably left dominant for speech. There is no information that suggests how the left-handed population would respond. Throughout the behavioral literature, the idea is implicit that right-dominant subjects can be considered a reverse case of left-dominant

subjects. However, there is no concrete reason to assume that the right-dominant person processes information as does the left-dominant person, except with the directionality reversed. To the contrary, Corballis and Beale (1976) suggested that left-handedness, except in cases of pathology, is due to the cancellation of asymmetry, not its reversal. This implies that those persons normally described as right dominant should more accurately be classified as bidominant. If this is true, then information processing and related performance of the left-handed population cannot be inferred from experiments that use only right-handed subjects. One method of determining the exact contribution of asymmetrical function to the performance of the rhythm tasks might be to compare the responses of strongly dominant (right-handed) subjects to those of bidominant (left-handed) subjects. This has not been done.

In addition, many of the cerebral dominance effect experiments infer cerebral lateralization from responses that require the accurate lateralization of auditory stimuli. This is a questionable practice. The cues that are normally used to determine laterality in audition are phase and intensity differences between the stimuli to the two ears. In most experiments, intensities of the stimuli to the two ears have been matched. However, phase has not been controlled in any rhythm experiment that has been reported in the literature; in fact, it is impossible to match phase when using stimuli of different frequencies or verbal stimuli.

To summarize, there is no way to determine which aspects or amounts of reported laterality or favoritism are due to differences in the acoustical attributes of the stimuli arriving at the two ears and to determine how much laterality is due to differential cerebral processing of those stimuli. It would be easy to suggest that the right-ear preference of left-dominant subjects for rhythm may be due to some sort of bias toward the phase information presented to that ear. This would not undermine the validity of the results of experiments in the current literature; it does, however, illustrate the type of problem that is faced when one attempts to interpret these results.

Continued studies of rhythm may increase our understanding of many complex cognitive functions. The elements that constitute rhythm, such as sequence, order, and relative duration, are probably not limited to the auditory modality. Colavita (1977) supported a hypothesis that the insular temporal cortex in cats (which is equivalent to Wernicke's area in the dominant human hemisphere) is a polysensory association area with special importance for the perception of temporal patterns. Although he found no evidence of asymmetrical hemispheric function in the animals, he concluded that temporal pattern discrimination appears to represent the basis or antecedents of the higher order perceptual abilities in humans that are not specific to any single modality.

Neisser (1967; see summary, pp. 279–305) anticipated this hypothesis. He suggested that rhythm provides a framework to which verbal information can be attached and that such a framework serves both to integrate incoming information and to expedite recall. Investigation of such a hypothesis has proved difficult because of the logistical problems of measuring rhythm components in verbal information. In view of the more recent research, it may be that rhythm structure provides a framework not only for verbal material, as Neisser proposed, but also for the synthesis and analysis of all incoming perceptual information.

Conclusions

1. Pitch perception is probably a direct result of the frequency properties of the stimuli. Therefore, pitch sensation alone does not require differential cerebral processing. Only when some type of novel or complex time structure is generated in the stimulus presentation are the responses of subjects influenced by handedness or cerebral dominance.

2. The cerebral dominance effect evident in the results of the few existing rhythm experiments closely parallels that found in verbal experiments. Since adequate stimulus control is easier to achieve when using tonal stimuli than when using verbal stimuli, results of further rhythm experiments may add substantially to our knowledge of language. In

addition, recent reports suggest that rhythm structure may also provide a framework for the synthesis and analysis of all incoming perceptual information. If this should prove true, it is difficult to assess the effects it might have on our knowledge of human information processing.

3. A review of this area serves best to emphasize what we do not know. There is currently a trend in the literature toward separate investigation of pitch and rhythm variables. This is probably an excellent approach, although it may be difficult or impossible to separate them operationally. However, it should be possible to define the processing mechanisms peculiar to each variable through careful, controlled experimentation. Only when this elementary information is obtained can we hope to make any definitive statement about how they interact in complex stimuli such as speech signals. Renewed effort should produce sizeable increases in our knowledge in the near future.

Practical Considerations in Choosing a MANOVA Test Statistic: A Rejoinder to Stevens

Chester L. Olson
Camrose Lutheran College, Alberta, Canada

The recommendation of the Pillai-Bartlett trace V for general use as the test statistic in multivariate analysis of variance (MANOVA) is reexamined and reaffirmed in light of criticisms by Stevens. Empirical data are presented to show that the V test's substantial robustness advantage does not require extreme violations of assumptions, and examples are cited to show the occurrence in practice of the type of heteroscedasticity in which the V test particularly excels and the occurrence of the pattern of population mean differences for which the V test is more powerful than its rivals.

In an earlier article (Olson, 1976), I presented evidence from power and robustness studies that the Pillai-Bartlett trace statistic V should be favored for general use as the test statistic in multivariate analysis of variance (MANOVA) and that Wilks's likelihood ratio W and the Hotelling-Lawley trace T could be considered equivalent to V in very large samples. Now Stevens (1979) has argued (a) that except in certain extreme cases, T and W are nearly as robust as V, (b) that such exceptions occur very infrequently in real data, and (c) that the V test should be used when there are population mean differences in several canonical dimensions of the multivariate space, but any of the V, W, or T statistics may be used when the population differences are concentrated in one dimension. The following discussion of these arguments serves to clarify some practical considerations in choosing a MANOVA test statistic and to underscore my earlier recommendation.

First, concerning the first argument: Is it only in extreme cases that V's robustness advantage is large enough to make much difference in practice? Stevens (1979, Table 1) shows empirical Type I error rates for 45 examples of heteroscedasticity from Olson (1973). When the contamination that produced the excessive variance in the one anomalous group was concentrated $[\mathbf{D} = \mathbf{C}(d)]$ in a single canonical variate, error rates for T, W, and V remained about equally close to the nominal level, although V was most often closest. When the anomalous group came from a population more variable in all dimensions $(\mathbf{D} = d\mathbf{I})$, the V test was almost always disturbed less than its rivals. Exploring the notion that V generally performed no more than 1.5 and 2.5 percentage points better than W and T, respectively, Stevens found that "eight of the nine cases in Table 1 in which the differences in error rates are larger. . . correspond to very large subgroup variance differences on all variables (36I)" (p. 355). There are two major reasons for this finding.

1. Stevens omitted some of Olson's (1973) examples of heteroscedasticity of the nonconcentrated type $(\mathbf{D} = d\mathbf{I})$. Table 1 of the present article gives Type I error rates for W and V in all the omitted examples for $d = 4$, 9, and 36. V bettered W by Stevens's criterion of at least 1.5 percentage points in 21 of the 26 cases, and of the 5 remaining cases, 3 would not be expected to show a difference because the sample sizes were very large relative to the number of variables (Olson, 1976, p. 583). Note that V surpassed Stevens's criterion even in cases in which the subgroup variance differences were not extreme ($d = 4$ and 9).

2. Olson (1973) examined far more cases with $d = 36$ than with any other value of d.

Table 1
Empirical Type I Error Rates for W *and* V *at the Nominal .05 Level When Variances in One Group Were* d *Times the Variances in the Other Groups*

			$d = 4$			$d = 9$			$d = 36$		
No. of variables	No. of groups	Group size	W	V	Difference[a]	W	V	Difference[a]	W	V	Difference[a]
2	6	50							163	162	001[b]
2	10	5							235	189	046[c]
2	10	10							208	194	014
3	3	5	080	067	013	134	093	041[c]	245	163	082[c]
3	3	50							098	094	004[b]
3	6	5	088	070	018[c]	162	100	062[c]	289	162	127[c]
3	6	10	092	077	015[c]	146	124	022[c]	224	186	038[c]
3	6	50							173	164	009[b]
3	10	5							307	167	140[c]
3	10	10							251	202	049[c]
6	3	5							489	092	397[c]
6	6	5							532	047	485[c]
6	6	10							361	177	184[c]
6	10	5							517	053	464[c]
6	10	10							356	171	185[c]
10	3	5							451	183	268[c]
10	6	5							707	073	634[c]
10	6	10							580	098	482[c]
10	10	5							732	051	681[c]
10	10	10							529	108	421[c]

Note. Data from Olson (1973). The decimal point preceding each digit triplet has been omitted; for example, 080 denotes .080.
[a] The standard error of such differences is approximately .007.
[b] W and V were almost equivalent because of the very large sample size.
[c] Differences of .015 or more.

The reader can verify from the data in Table 1 (and in Stevens's Table 1) that as d increased from 1 (at which point the actual error rate equals the nominal level) to 4 to 9 to 36, the actual error rate increased regularly, with a tendency to increase proportionately more in the range from 1 to 9 than in the range from 9 to 36. Thus one can get a fairly good idea of error rates and differences between error rates at intermediate values of d by interpolation between $d = 1$ and $d = 36$. Any reasonable interpolation in Table 1 shows that d does not have to be nearly as extreme as 36 for V to be markedly superior to W for small to moderate sample sizes.

Let us turn now to the second argument: Is it true that the d**I** pattern of heteroscedasticity, in which one population is more variable than the others in all dimensions, occurs very infrequently in practice? To support an affirmative answer, Stevens summarized real data from nine investigations. (Actually, one of the nine is not quite real: Smith, Gnanadesikan, and Hughes, 1962, arbitrarily divided their data into the four groups "just for illustrative purposes" [p. 28].) Of course, with real (sample) data, one has no way of being sure what the underlying populations looked like, but even in Stevens's intended counterexamples, there is evidence of the type of heteroscedasticity in question: Wright's (1975) first group was more variable on all nine subtests than the other three groups, which had approximately equal variances.[1] This example suggests the d**I** pattern of heteroscedasticity with $d \approx 2.2$. In Meichenbaum's (1975) data from the three subscales of the consequences test, variances were largest for the self-instructional group but unequal for the other two

[1] Note that the variance on the spelling subtest for girls in a traditional school was erroneously reported in Stevens's article as 2.25 rather than 1.82.

groups, as noted by Stevens. Data not reported by Stevens from the same experiment revealed that the self-instructional group was more variable on all three subscales of the unusual uses test than the other two groups, which were about equally variable, suggesting non-concentrated heteroscedasticity with $d \approx 1.9$. The values of d are small, but these examples illustrate that the $d\mathbf{I}$ pattern of heteroscedasticity is entirely realistic.

Finally, concerning the third argument: What recommendation can be made to guide the MANOVA user? Stevens correctly noted that in terms of power, the preferred test depends on whether the noncentrality, or inequality of population means, is (a) heavily concentrated in one canonical variate, in which case the T and W tests are more powerful than V, especially with more than five or six variables, or (b) more diffuse, appearing in several dimensions, in which case the V test is more powerful even if the noncentrality is not distributed equally across the several dimensions (Olson, 1973; Schatzoff, 1966). Nor can one refute Stevens's inference that concentrated noncentrality is probably common in behavioral research. However, there is also evidence that moderately diffuse noncentrality is by no means uncommon in practice (e.g., Bock, 1975, p. 408; Jones, 1966, pp. 258–265; Overall & Klett, 1972, pp. 285–292), and since noncentrality is a property of the population, not of the sample, the experimenter has no way of knowing for certain which form of noncentrality, if any, exists in a particular population of interest. If significance levels are to mean anything, it is certainly not appropriate to choose one's test statistic on the basis of the sample outcome that is to be tested! Thus the experimenter, faced with real data of unknown noncentrality and trying to follow Stevens's recommendation to use V for diffuse noncentrality and any of the V, W, or T statistics for concentrated noncentrality, must always choose V, a choice compatible with my original recommendation (Olson, 1976, p. 585).

In summary, the V test is sometimes more powerful than W or T and sometimes less powerful, but it is consistently more robust, sometimes by a substantial margin, and all of these situations are realistic possibilities in practice. It must be noted that the conclusion to be drawn from these facts depends on one's relative distaste for Type I and Type II errors, and my own preference is to ensure that the Type I error rate remains close to the nominal level. Therefore, the V test is recommended for routine use.

Index of Literature Reviews and Summaries in the *Psychological Bulletin*, 1967–1978

Ludy T. Benjamin, Jr., and Leigh S. Shaffer
Nebraska Wesleyan University

This index updates a previous compilation by Thomas Andrews and Frances Kerr, which was published in 1967 in the *Psychological Bulletin* (*68*, 178–212), covering the years 1940–1966. The *Psychological Bulletin* has continued to be the major source of literature reviews and summaries on topics of interest to psychologists, and the present index was designed to facilitate access to that material. Like the earlier index, the current one includes all articles that were wholly or largely reviews of a specialized area of literature. Published comments on those review articles have also been included. Those articles that were judged not to qualify as literature reviews were excluded from this index. The author index is completely cross-referenced. Articles are designated by author, volume number, and page number(s). In the subject index, the number of items in the reference section of each article is also provided. The letter *P* following a subject listing indicates that the particular subject is only part of the review article. In preparing the subject index the articles were cross-referenced on a large number of headings in an attempt to make topical retrieval by the researcher as fruitful as possible.

Index of Reviews and Notes on Statistical Methods and Research Design in the *Psychological Bulletin*, 1967–1978

Leigh S. Shaffer and Ludy T. Benjamin, Jr.
Nebraska Wesleyan University

This index updates the previous index of reviews and notes on statistical methods and research design compiled in 1967 by Thomas Andrews and published by the *Psychological Bulletin* (*68*, 213–220). This index complements the index of literature reviews and summaries by including useful treatments of statistical procedures and research design considerations that did not qualify as literature reviews. Organization of this index is identical to that of the index of literature reviews and summaries and articles on topics of statistics and research design that are included in the larger index are also included in this index.

Miller Appointed Editor, 1981–1986

The Publications and Communications Board of the American Psychological Association announces the appointment of George A. Miller as editor of *Psychological Bulletin* for the years 1981–1986. As of January 1, 1980, manuscripts should be directed to the Editor-elect:

George A. Miller
